The influence of diffusivity is illustrated by creep tests on body-centered cubic α iron just below 910 °C and face-centered cubic γ iron just above 910 °C. The α iron creeps at ca. 200 times the rate of the γ iron, reflecting their relative rates of self-diffusion [15]. The mechanisms that increase creep strength are discussed in Section 3.1, and typical creep rupture data for various metallic systems are shown in Figure 9.

Figure 9. Creep strength relationships for metal systems
a) Al (RR 58); b) Ti (Ti – 5 Al – 2.5 Sn); c) Fe (A 286); d) Ni (Inco 713 C); e) Mo (Mo – 0.5 Ti)

Creep is experienced by components that operate at high temperature under load. Turbine

rotor blades experience temperature and stress conditions in the aerofoil such that creep is likely to determine blade life. Another aspect of creep is evident in components such as bolts in turbine casings. Here creep produces a stress relaxation with time and the bolts must be retightened at intervals.

2.6. Mechanical Fatigue

Mechanical fatigue is a common failure mechanism that can occur when a component or structure is subjected to repeated stress or strain cycles, with failure occurring at a stress well below the tensile strength of the material. Fatigue is often classified as high-cycle or low-cycle fatigue. In *high-cycle fatigue*, the operating stresses are below the general yield stress of the material, and failure, often caused by local stress concentration, occurs after $>10^4$ cycles. In *low-cycle fatigue,* the stress levels are above the general yield, and fracture generally occurs in $<10^4$ cycles [16]. Operation often involves an extended period under load in the normal fatigue cycle (dwell on load) as, for example, in an airframe structure that is pressurized and depressurized during each flight. Temperature reduces material strength and, consequently, fatigue strength, but an additional effect can occur in low-cycle fatigue. Dwell on load at temperature can further reduce life by a creep – fatigue interaction that may result in accelerated growth of fatigue cracks.

2.7. Thermal Fatigue

In thermal fatigue, stresses are generated by temperature cycling. In the extreme case referred to as *thermal shock*, a ceramic may be subjected to a temperature change of sufficient magnitude for the resultant thermally induced stress to cause failure in one cycle. Although ductile metals are more resistant to thermal fatigue than other materials, failure can occur solely from thermally generated stress. More commonly, components operating in high-temperature machinery, such as the rotor blades in gas turbines, experience a combination of thermally induced and direct stresses. Such creep fatigue interaction is referred to as thermo-mechanical fatigue. Component life under such conditions can be predicted from testing in which direct stress and temperature cycling appropriate to component operation is applied to test samples[17]. Thermo-mechanical fatigue life can be maximized by selecting materials with the most appropriate property combination, including physical properties that minimize thermally generated stress. This last requirement is satisfied, for example, (1) by the glass ceramic lithium aluminum silicate, which has a low coefficient of thermal expansion, and (2) by directionally solidified nickel superalloy turbine blades, which have a Young's modulus lower than that of conventionally cast blades.

2.8. Oxidation

The tendency of a metal to react with oxygen either directly or indirectly is indicated by the *thermodynamic free energy change* ΔG accompanying oxide formation. Free energy changes for metal oxides are shown in Figure 10. The more reactive metals, and thus the more stable oxides, are found toward the bottom of the diagram. The rate of oxide formation is determined by *reaction kinetics*, which in turn depend largely on the nature and properties of the oxide. After initial chemisorption of oxygen atoms, the nucleated oxide grows until an oxide film composed of multiple grains covers the surface. The oxide film acts as a barrier to further oxidation. Some oxides, such as MoO_3 and WO_3, are volatile and thus offer no protection against oxidation (Fig. 11, curve a). If the oxide film is porous, oxygen can pass through it and react at the metal – oxide interface so that oxidation continues (Fig. 11, curve b). Usually, however, the oxide is not porous and further oxidation can occur only because metal ions diffuse through the oxide to the oxide surface or because oxygen ions diffuse through to the metal. The rate of diffusion and consequent rate of oxidation depend on temperature and defects in the oxide lattice. The extent of oxidation normally decreases with time (Fig. 11, curves c); good protection is provided by Al_2O_3 on aluminum and Cr_2O_3 on stainless steel. Initially protective oxides may become ineffective due to factors such as cracking or spallation (Fig. 11, curve d) which are caused by an inability to accommodate the stress from the growing volume of oxide relative

to the volume of metal from which the oxide is formed.

Figure 10. Free energy change ΔG for oxide formation

Figure 11. Schematic representation of oxidation behavior

Nonoxide ceramics are attacked in oxidizing atmospheres but the oxide formed may provide some protection. Silicon carbide and molybdenum disilicide are protected by the SiO_2 surface layer and are used extensively for heating elements. Secondary phases arising from the metallic oxides added to silicon nitride to aid densification during sintering can reduce the protection afforded by the SiO_2 because of the formation of complex surface glasses. Most oxide ceramics are unaffected by oxidizing atmospheres; however, the use of silicon-based ceramics under high-temperature reducing conditions is limited by the formation of volatile SiO.

In practice, the solid – gas reaction is more complex than the simple metal – oxygen reaction and involves gaseous mixtures (e.g., combustion products from jet engines or rocket nozzles). Elements such as sulfur, sodium, vanadium, and carbon that are present in the atmosphere or the fuel can participate in corrosion.

2.9. Hot Corrosion

Hot corrosion denotes the accelerated oxidation of nickel or cobalt superalloys that occurs when the alloys are exposed to high temperature and the surface becomes coated with foreign deposits such as Na_2SO_4, V_2O_5, or NaCl. These deposits may come from the environment, or they may be present as contaminants in the fuel. Gas turbines operating close to the sea ingest sea salt, which reacts with sulfur in the fuel to form Na_2SO_4. Sulfides can take part in the hot corrosion process, whose rate reaches a maximum at 800 – 900 °C, depending on alloy composition; this process can be much more severe than basic oxidation at the same temperature (Fig. 12). Formation of chromium sulfides is common with nickel superalloys and results in localized chromium depletion with a detrimental influence on oxidation resistance. The sulfides are then oxidized, and the liberated sulfur penetrates further into the alloy to produce sulfides, which are reoxidized. The process continues with a progressive increase in corrosion rate because the chromium is unable to reform a protective surface film.

A type of corrosion known as *sulfidation* can occur in the low-oxygen atmospheres found in gasification plants operating on coal or oil. Such atmospheres contain appreciable amounts of sulfur, and conditions can be such that protective oxide scales are not formed. Sulfide scales are not protective because they are mechanically less stable than oxides; they allow diffusion rates

Figure 12. Oxidation and hot corrosion of nickel superalloys

several orders of magnitude faster than oxidation, probably because of the relatively low melting points of sulfides.

Accelerated oxidation can occur from a flux in the Fe_2O_3 film formed on the superheater tubes of coal-fired power plant boilers; sulfides are not involved in the corrosion process. Ash from the combustion is deposited on the superheater tubes. A protective oxide forms under the ash, but sulfates gradually accumulate at the base of the porous ash deposit. The mixed sulfate remains molten at tube surface temperatures $>600\,°C$ and forms a thin layer of extremely corrosive liquid adjacent to the protective oxide scale. This layer contains free SO_3, which reacts with the oxide to form more sulfate, ensuring continued corrosion [18].

2.10. Carburization

Carburization may occur in nickel alloy furnace equipment in low-oxygen atmospheres containing significant concentrations of carbon monoxide, methane, and other hydrocarbons (e.g., in the carburizing process used to case-harden steel). Carbon is absorbed onto the surface from the gaseous phase and diffuses into the base metal to produce carbides (usually of chromium). These carbides reduce ductility, thereby increasing the possibility of cracking under thermal cycling conditions, as well as the possibility of oxidation or sulfidation by reducing the level of available chromium in the base material.

2.11. Erosion

Erosion is the mechanical removal of material by a moving fluid, usually containing solid particles. An example is the severe damage to compressor blades experienced by turbines in helicopters operating in dusty terrain. Erosion at high temperature can be more or less severe than at room temperature, depending on the relative erosion resistance of the oxide scales and base material. Particulate erosion and chemical corrosion often occur simultaneously (e.g., in fluidized-bed coal combustion systems for electric power generation).

2.12. Wear

Wear takes place during the relative motion between two surfaces and has been a consistent cause of component damage in many applications. *Abrasive wear* is caused by hard particles such as metallic debris or oxides. *Adhesive wear* (or galling) is caused by shearing of the microwelds formed at mating surface asperities; wear

debris is removed from the weaker of the two mating surfaces. The type and severity of wear are determined by applied load, relative movement of contacting surfaces, impact effects, temperature, etc. In discussing the effects of temperature, a distinction must be made between the temperature of the environment and the localized high temperatures of short duration that are generated by friction. Wear tends to be less severe at high temperature because of the beneficial effects of the oxides formed, provided they adhere to the surface. Poor oxide adherence can give rise to *oxidative wear.*

3. Mechanisms for Increasing Temperature Capability

3.1. Metallic Materials

Several mechanisms have been used to strengthen metallic materials by impeding the movement of dislocations, thus reducing deformation under load. Solid-solution strengthening is applicable in different degrees to all base metals. Strengthening by precipitation of second phases is effective but not possible in all alloys. Incorporation of dispersions of stable particles can increase strength considerably at very high temperature. Grain boundaries play a significant role in determining strength; a fine grain size is generally beneficial in the lower temperature creep region, and a coarser grain size tends to improve strength in the higher temperature creep region.

3.1.1. Solid-Solution Strengthening

A solid solution forms when atoms in the crystal lattice of one metal are replaced by atoms of another metal. The extent of solid solution depends on the atoms involved and is normally greater with atoms of similar size and electron structure. If the diameters of the two atoms differ by more than ca. 15 %, the amount of solid solution is small. The greater the discrepancy in electron structure, the greater is the tendency to form compounds rather than extensive solid solutions. *Strengthening* is due to internal strains generated by the presence of solute atoms. Atoms with similar lattice parameters may have high mutual solubility but provide relatively little strengthening. Atoms with different lattice parameters may have limited solubility, but low concentrations could produce significant strengthening. For similar lattice strains, the larger the valence difference between solute and solvent, the greater the strengthening.

Very few elements have sufficient solubility in aluminum to develop effective solid-solution hardening, and the effect is small compared with precipitation hardening (see Section 3.1.2). Nickel has a much greater scope for solid solution strengthening. Aluminum, tungsten, and molybdenum are effective solid-solution strengtheners. Strengthening persists to high temperature, but in the creep regime above $0.6\,T_{\mathrm{m}}$, diffusion effects become more important; molybdenum and tungsten are effective in lowering diffusion rates.

3.1.2. Precipitation Hardening

Precipitation of a second phase occurs in many alloy systems as a result of a decrease in the solid solubility of alloying elements with decreasing temperature. In the reverse process, the phase dissolves as the temperature rises above the solvus temperature for the precipitate. If the material is then cooled rapidly (e.g., quenched), precipitation is suppressed and the alloy exists at low temperature as a supersaturated solid solution. If material in this condition is allowed to age at ambient or higher temperature (depending on the alloy system), the second phase precipitates. This can provide a major strengthening mechanism in high-temperature materials such as aluminum alloys, nickel superalloys, and steels. The mechanism is illustrated in Figure 13.

The strengthening ability of the precipitate depends on its compatibility with the matrix (e.g., crystal structure and lattice parameter) and also on the volume fraction of the precipitate and its size. Relatively small differences in lattice parameters allow coherence between precipitate and matrix of similar crystal structure; i.e., the two structures match at the interface, with the degree of distortion depending on the amount of mismatch in lattice parameters. Precipitates that do not show coherence with the matrix provide less strengthening. Nickel super-

Figure 13. Schematic representation of precipitation hardening
A) Typical microstructures: the black dots represent $CuAl_2$ precipitate; B) Phase diagram

alloys can be strengthened by precipitates based on Ni_3Al, usually referred to as γ'. The γ nickel matrix and the γ' Ni_3Al precipitate have similar crystal structures, and if the mismatch in lattice parameters does not exceed ca. 1 %, the precipitate is an effective strengthener. Besides providing different degrees of solid-solution strengthening, alloying additions can modify coherency strains by modifying the lattice parameter of the phase in which they are partitioned. The effect of $\gamma - \gamma'$ mismatch on hardness for different alloys is shown in Figure 14 [19]. Precipitates with higher mismatches tend to be less stable and thus less effective in increasing temperature capability than lower mismatch precipitates.

The precipitates strengthen by impeding the progress of dislocations through the material. When they reach the precipitates, dislocations either must bypass them by climbing or looping or must cut through them. Both mechanisms operate and there is an optimum precip-

Figure 14. Effect of $\gamma - \gamma'$ mismatch on hardness of nickel – aluminum ternary alloys after aging at 870 °C for 50 h

Figure 15. Relationship between γ' particle diameter and hardness of Ni – 22 Cr – 2.8 Ti – 3.1 Al alloy after age hardening at 750 °C

itate size (Fig. 15) [20]. Strength also increases with increasing volume fraction of precipitate (Fig. 16) [21]. Some alloying elements influence the solubility of the precipitating phases. For example, the addition of cobalt increases the solvus temperature of γ' and thereby increases the creep strength of Nimonic 90 over the cobalt-free Nimonic 80 (Fig. 17).

Figure 16. Effect of γ' volume fraction on 100-h creep strength of a nickel superalloy
a) 705 °C; b) 980 °C

Figure 17. Creep strength of Nimonic 80 A and Nimonic 90: rupture in 300 h

In aluminum alloys, changes in the early stages of the precipitation process produce peak hardening (→Aluminum Alloys, Chap. 2.3.3.). Large numbers of ordered solute-rich clusters of atoms, possibly only one or two atom layers thick, are formed in zones known as *Guinier–Preston* (*GP*) *zones*. These zones retain the structure and coherence of the matrix and usually produce appreciable elastic strain. An intermediate precipitate (e.g., tetragonal $CuAl_2$ in Al–Cu, hexagonal Mg_2Si in Al–Mg–Si) is subsequently formed, which is much larger than a GP zone and has only partial coherence with the matrix so that strengthening is somewhat lower [22]. Formation of the final precipitate (body-centered tetragonal $CuAl_2$ in Al–Cu, face-centered cubic Mg_2Si in Al–Mg–Si) involves complete loss of coherence with consequent reduction in strength. The precipitation reactions can be influenced greatly by the presence of small amounts of certain elements that can modify phase behavior or promote precipitate formation [23].

The solvus temperature of a GP zone broadly defines the upper temperature limit of stability. In some alloys, GP zones act as nuclei for the subsequent stage of the aging process, usually the intermediate precipitate [23,24]; this is exploited in two-stage (duplex) aging. In other alloys, the intermediate precipitate nucleates heterogeneously at lattice defects such as dislocations.

Precipitation reactions occur in low-alloy and 12 % chromium martensitic steels during the tempering of martensite. In low-alloy steels, Mo_2C, V_4C_3, and TiC lead to precipitation hardening. As with aluminum alloys, the sequence of reactions in the precipitation hardening of steels (also known as secondary hardening) is usually the formation of zones followed by intermediate precipitates and equilibrium precipitates [25]. The intermediate precipitates generally form at 450–600 °C with a coherent matrix interface. The equilibrium carbide phases do not usually form below ca. 650 °C and have incoherent interfaces with the matrix [26].

In 12 % chromium steels, secondary hardening is due to the precipitation of a chromium-rich carbide of the M_2X type. Alloying elements such as molybdenum and vanadium can stabilize this carbide, and increase the temperature range over which it forms, the associated coherency strain, and thus secondary hardening [27]. The effect of molybdenum and vanadium on the temper resistance of a 0.1 C–12 Cr–2 Ni steel is shown in Figure 18.

Figure 18. Influence of alloying elements on the temper resistance of 12 % chromium steels
a) Base steel 0.1 C – 12 Cr – 2 Ni; b) Base steel containing 1 wt % vanadium; c) Base steel containing 3 wt % molybdenum

3.1.3. Dispersion Strengthening

In precipitation-hardening systems, the precipitated phases redissolve above their solvus temperature, thus placing a limit on their temperature capability. The incorporation of phases that are insoluble in the base alloy, such as Al_2O_3 in aluminum and ThO_2 in nickel, allows strengthening at a temperature above that where precipitation hardening is effective. Strengthening is somewhat less than in precipitation-hardened material because the dispersed phase is not coherent with the matrix. Strengthening can, however, still be significant provided the dispersed phase has a fine, uniform distribution with the necessary interparticle spacing. Thus dispersion-strengthened alloys have a relatively flat strength – temperature curve compared to precipitation-hardened alloys (Fig. 19). The dispersed phases impede dislocation movement, and strengthening is increased by controlled mechanical working to produce the optimum microstructure that is stabilized by the dispersion.

The ability of dispersed phases to stabilize grain structure was applied at one time to tungsten lamp filaments which operate at ca. 2500 °C (0.8 T_m) and must be substantially free of distortion. Incorporation of ca. 1 % ThO_2 inhibited the recrystallization and grain growth that led to failure in pure tungsten filaments. The thorium dioxide dispersion has since been replaced by an alternative technology (Chap. 8).

Figure 19. Comparison of 100-h creep rupture of precipitation-strengthened (Nimonic 80 A) and dispersion-strengthened (TD nickel) nickel superalloys

3.1.4. Grain Boundary Effects

A *grain boundary* is a region of mismatch between the atomic lattices of adjacent grains, in which the mismatch produces less efficient local atomic packing. This boundary impedes the progress of dislocation movement and thus provides a strengthening mechanism at temperatures up to ca. 0.5 T_m. Below this limit, the influence of grain size on yield strength is given by the *Hall – Petch relation*:

$$\sigma_y = \sigma_i + K_y d^{1/2}$$

where σ_y is the yield strength, σ_i is a lattice friction term, K_y is the dislocation locking term and $2d$ the grain diameter. Controlled thermomechanical processing has been used to reduce grain size and to improve tensile and fatigue strength in nickel superalloy disks for gas turbine engines. Data for Rene 95 are given in Table 3 [28].

Table 3. Effect of grain size on tensile strength of Rene 95

Heat treatment, °C	Grain size, µm	Tensile strength	
		0.2 % YS [b], MPa	UTS [c], MPa
1120 AC [a]	5	1130	1500
760 AC	5	1130	1500
1220 AC	150	920	1250
1120 AC	150	920	1250
760 AC	150	920	1250

[a] AC = air-cooled.
[b] YS = yield strength at 650 °C.
[c] UTS = ultimate tensile strength at 650 °C.

Above ca. 0.5 T_m, diffusion becomes significant and the grain boundaries can act as sinks for dislocations; the rate of diffusion in the grain boundary region can be several orders of magnitude higher than in the grains themselves. Thus, at high temperatures, grain boundaries have a weakening effect, and an increase in grain size is normally accompanied by an increase in creep life. The effect of grain size on the creep life of a wrought nickel superalloy is shown in Figure 20 [29]. Test piece dimensions relative to the number of grains in the section under load are also important. The extent of grain boundary weakening can be reduced by microstructure control. For example, some grain boundary carbides in nickel superalloys inhibit grain boundary sliding and thus increase creep strength. Very low carbon content can give rise to inadequate carbide levels, which result in low tensile strength and ductility with intergranular failure [30]. Excessive levels of carbon can result in continuous grain boundary carbides and consequent brittleness. Most nickel superalloys contain 0.05–0.15 % carbon. The carbide–matrix interface can be a source of weakness, although a grain boundary film of Ni_3Al (see Fig. 44) can protect this interface. Further grain boundary strengthening can be achieved by the addition of small amounts of boron and zirconium, which segregate to grain boundaries and reduce diffusion rates (Table 4) [31].

Figure 20. Effect of grain size and test piece diameter on creep rupture life of a wrought nickel superalloy at 150 MPa and 870 °C
Grain size: a) 8 µm; b) 23 µm

One way of avoiding the high-temperature weakening due to grain boundaries is to eliminate them. Directional solidification produces castings with aligned columnar grains. If the boundaries between the grains are in the direction of the principal applied stress, their effect is minimized and a significant increase in creep life and ductility is achieved [32]. Elimination of grain boundaries by the production of single-crystal components further increases life (Fig. 21). The lower secondary creep rate shown in Figure 21 (curve c) is essentially due to the more effective use of the γ' precipitate in single-crystal materials (see Section 7.3.1).

Table 4. Effects of boron and zirconium on creep properties of Udimet 500

Alloy	Creep life at 175 MPa and 870 °C, h	Rupture elongation, %
Udimet 500 base alloy	50	2

a) Conventionally cast Mar M 002; b) Directionally solidified Mar M 002; c) Single-crystal SRR 99 nickel superalloys

3.2. Nonmetallic Materials

In contrast to metallic materials, which deform by dislocation movement and are strengthened by making movement more difficult, few high-temperature, nonmetallic materials are able to deform plastically in zero time. Room-temperature tests on polycrystalline MgO produced fracture at <1 % plastic strain, and the behavior was essentially brittle. Dislocation movement led to crack nucleation, growth, and cleavage failure.

Most high-temperature ceramics have complex crystal structures and do not deform plastically. Therefore, they cannot relieve local stress concentrations and are sensitive to the presence of defects such as pores and small cracks. The

problem in such materials is to find ways of developing consistent, useful strength levels. Elimination of all defects is impractical. Even if a defect-free material could be produced, some stress concentration features and defects would certainly develop during use. The practical approach is to develop defect-tolerant ceramic materials for use in applications involving significant stress levels (see Section 9.3.4).

Most manufacturing processes reduce the temperature capability of the ceramic below that theoretically possible for the pure ceramic. For example, the sintering aids added to Al_2O_3 lower strength and softening temperature compared with pure Al_2O_3. Temperature capability can be maximized by selecting the production process and material composition so that the minimum temperature decrease is achieved relative to the pure ceramic.

3.3. Corrosion-Resistant Coatings

(→Corrosion; →Metals, Surface Treatment)

3.3.1. Aluminum

Aluminum oxidizes to form a protective film of Al_2O_3. The oxide that forms on freshly exposed aluminum is thin, and thicker oxide films with better protection capability can be formed by chemical or electrochemical treatment. Film thicknesses of ca. 1 – 2 µm can be formed by chemical treatment and can incorporate substances such as chromates to improve corrosion resistance. Electrolytic anodizing produces films 10 to 20 µm thick, but in the most severe environments (e.g., jet engine compressor blades in salt-containing environments), corrosion resistance may be inadequate and the anodized surface can be treated with a phenolic or an epoxy resin. Cladding with a more corrosion-resistant aluminum alloy is also used to give protection in certain applications (see Section 4.1.1).

3.3.2. Steel

Low-alloy steels have poor high-temperature oxidation resistance because the FeO or higher oxide formed provides inadequate protection. Several types of protection are used for steels [33]. Chromized coatings are applied by a pack cementation process, the pack consisting of chromium or ferrochromium powder, a halide activator, and an inert powder diluent such as Al_2O_3 or Cr_2O_3. Chromium diffuses into the steel surface at ca. 1000 °C, creating a protective layer of Cr_2O_3 that forms on high-temperature oxidation rather than the less protective iron oxides.

Phenolic or epoxy resin coatings physically separate the steel surface from the oxidative or corrosive atmosphere. They can be used up to 200 °C; their temperature capability increases to ca. 500 °C when they are filled with aluminum powder. Such coatings do not provide cathodic protection. This can be developed when aluminum-filled inorganic paints based on silicate or phosphate binders are made electrically conducting by peening or low-temperature heat treatment. Such coatings are necessary to avoid the severe corrosion found on jet engine compressor components that operate in sea salt ingestion conditions. Electroplated coatings based on nickel and cadmium have also been used in such applications.

3.3.3. Nickel

The types of corrosion against which protection is required are discussed in Sections 2.8 and 2.9; corrosion resistance is provided by the stable protective oxides Cr_2O_3 and Al_2O_3. The base nickel alloy may have the necessary inherent corrosion resistance in some applications, but the highest temperature oxidation and most severe hot corrosion environments require protective coatings containing higher amounts of aluminum and chromium. The protective effect of Cr_2O_3 is limited to a maximum temperature of ca. 1000 °C due to the formation of volatile CrO_3; Cr_2O_3, provides the best protection against hot corrosion, whereas Al_2O_3 provides the best protection against oxidation.

Coatings on nickel superalloys are either diffusion or overlay types. *Diffusion coatings* are applied by pack cementation processes in which the part is surrounded by powdered aluminum- or chromium-rich material, a halide activator, and an inert powder diluent [34]. A chemical vapor deposition mechanism transfers aluminum at ca. 700 – 1100 °C and chromium at ca. 1000 °C to the part surface. These diffuse

Figure 22. Microstructures of aluminide and overlay coats
a) NiAl; b) CoAl or NiAl dispersed in nickel or cobalt solid solution

from the surface into the base material to form a nickel aluminide or nickel – chromium solid solution, which may contain α-chromium particles. The composition of the coating is influenced significantly by the base material because of diffusion. Coating composition and thickness are also determined by the pack composition, process temperature, and any heat treatment after coating. A typical aluminide coating is 50 µm thick and contains >30 % aluminum. A typical microstructure is shown in Figure 22. The protection provided by aluminide coats is illustrated in Figure 23. Aluminide coats were introduced in the early 1960s and are still used on gas turbine rotor and stator blades and on other nickel superalloy components.

Figure 23. Uncoated (A) and aluminized (B) gas turbine blades after hot corrosion operation
The uncoated turbine blade (A) shows the degree of hot corrosion after 2500 h of service between airfields with low sea approaches and relatively short sector times. The aluminized blade (B) shows virtually no corrosion at a similar lifetime [33].

Improved coatings are, however, required for the highest temperature oxidation and the most severe hot corrosion environments. This need has resulted in the development of improved aluminides and the MCrAlY overlay coats. One of the most important modified aluminide coats is *platinum aluminide* [34]. A thin layer of platinum is applied to the component surface and aluminized. Platinum improves protection by introducing a platinum aluminide phase into the coating microstructure and by stabilizing the nickel aluminide phase.

Overlay coats [35] differ from aluminide coats in that the material is deposited on the component surface, usually by electron-beam physical vapor deposition, or a low-pressure or argon-shrouded plasma spray. Coating composition is independent of base material composition, although significant interdiffusion can occur during subsequent high-temperature service. A wide range of MCrAlY compositions is available in which the base coating element M can be nickel, cobalt, or iron. Chromium (15 – 30 %) and aluminum (6 – 12 %) provide corrosion resistance. Yttrium improves oxide scale adherence, which is particularly important during thermal cycling; similar effects have been found with cerium (Fig. 24) [36]. Several models have been proposed to explain the improved adhesion resulting from the addition of rare-earth elements [37].

Figure 24. Effect of cerium on the isothermal and cyclic oxidation of Ni – 50 Cr at 1100 °C

Coating thickness is normally 100 – 150 µm, and composition depends on the environment against which protection is required. A CoCrAlY coating with high chromium and low aluminum that forms Cr_2O_3 may be better in hot corrosion conditions, whereas a CoNiCrAlY coating with high aluminum and low chromium that forms Al_2O_3 may be better against oxidation. (A typical MCrAlY microstructure is shown in Figure 22.) Addition of small amounts of silicon, hafnium, and tantalum is reported to improve oxidation resistance. Coatings may be degraded by several mechanisms during high-temperature operation. The oxide-scale-forming elements chromium and aluminium are reduced by progressive oxide formation and spallation and also by diffusion from the coating into the base material, particularly at the highest temperatures. Depending on operating conditions, coatings may also experience mechanical or thermal strains. These strains can result in cracking in the coating, particularly in highly stressed components such as turbine rotor blades in military jet engines. Improved life to cracking was achieved initially by increasing coating ductility. Although the ductility of aluminide coats depends on composition, overlay coating compositions can be selected to provide higher levels of ductility than are possible with aluminide coats (Fig. 25). This was found to be significant in extending life to cracking in severe thermal cycling. More recently, coating life has been predicted from thermo-mechanical fatigue tests.

Figure 25. Effect of coating composition on ductile – brittle transition temperature

3.4. Insulating Coatings

Thermal barrier coats (TBCs) based on ZrO_2 have been used on combustion chamber walls of jet engines since the mid-1970s and are being evaluated in diesel engines. In jet engine combustors, TBCs have produced local temperature reductions of 50 °C or more, and combustor life has more than doubled [38]. In diesel engines, components such as pistons, valves, and liners have high surface temperature. More than 55 % of the energy produced by combustion is lost through the cooling system and exhaust gas, reducing efficiency [39]. Use of TBC cuts the heat loss from combustion chambers by 50 – 80 %, depending on coating thickness [40], and thermal efficiency is improved by > 30 %.

A thermal barrier coat must have (1) low thermal conductivity, (2) resistance to the corrosive environment, (3) thermal shock resistance, and (4) a coefficient of thermal expansion compatible with the metal substrate. Zirconium dioxide meets these requirements, with a thermal conductivity that is about one-tenth that of nickel superalloys and cast iron. The ZrO_2 must be stabilized because a phase change occurs at 1170 °C, with the tetragonal form transforming to monoclinic on cooling. This phase change generates

a volume expansion of ca. 4 %, creating large shear strains that can lead to cracking. A MgO-stabilized ZrO_2 was initially used in jet engine combustors, but some destabilization occurs on long-term soaking above 1000 °C. Full stabilization with 20 % Y_2O_3 is possible, but partial stabilization with 8 % Y_2O_3 to a nonequilibrium tetragonal phase with high-temperature capability gives the best performance in jet engine applications [38]. An oxidation-resistant bond coat is included because ZrO_2 does not protect the substrate metal from oxidation. This also accommodates the interface strains arising from thermal expansion differences. Early bond coats were based on the Ni – Cr system, with more recent coats being of the MCrAlY type. The microstructure of a typical TBC is shown in Figure 26.

Figure 26. Typical microstructure of plasma-sprayed thermal barrier coat (TBC)

Bond coats are normally applied by plasma spray processes, and spraying under low pressure is necessary for the more oxidation resistant compositions. Plasma spraying in air has been the standard process for applying the zirconia coatings, but physical vapor deposition (PVD) has subsequently been used for applying TBCs in the more severe turbine rotor blade applications [41]. The columnar structure produced by the PVD process minimizes stress development in the ceramic coating.

The prime cause of failure in TBCs is the stress developed due to the differential thermal expansion between ceramic and metal during thermal cycling. Failure occurs at the interface between the ceramic and the bond coat. The major factors controlling life are the maximum temperature and the severity of the thermal cycling, and life-prediction methodology has been developed [42].

3.5. Wear-Resistant Surfaces

Lubrication is probably the most common technique for reducing wear by lowering friction and separating the contacting surfaces. Liquid lubricants are limited to ca. 250 °C by their thermal stability. Solid lubricants are used at higher temperature, with $MoSi_2$-based materials being used up to 300 °C and graphitic lubricants to 400 °C.

Many situations require the use of wear-resistant surfaces. Such surfaces can be produced on steels by thermochemical diffusion processes such as carburizing or nitriding. Nitriding has the higher temperature capability because nitriding steels are normally more temper resistant than carburizing steels. Nitrided surfaces can be used up to 500 – 600 °C, and one of the earliest applications was to improve the life of high-speed steel machining tools. The temperature of the cutting edge can exceed 700 °C under some conditions, and nitriding increases tool life up to 500 % [43]. Hot extrusion dies and pistons in the Stirling engine are other applications. Nitriding can be carried out by gas, salt bath, or plasma techniques [44–46].

General requirements for high-temperature, wear-resistant coatings include hardness, toughness, strength, and corrosion resistance. Specific requirements depend on the particular wear environment; for example, hot hardness is more important in high-impact loading. Most coatings contain stable carbide-forming elements (e.g., chromium, tungsten, and vanadium), with hardness increasing and toughness decreasing as the carbide volume fraction increases. The binder phase is commonly cobalt, cobalt – chromium, or nickel – chromium, depending on the corrosion resistance and toughness required. One factor contributing to the performance of cobalt-based coatings is the beneficial effect of cobalt oxides formed during high-temperature wear. Coatings are applied by weld deposition, electroplating, flame spraying, or a detonation gun [47]; examples of the potential improvement relative to uncoated materials are shown in Figure 27. Applications include Cr_3C_2 – NiCr and hard cobalt-based, heat-resisting alloys on turbine blade shroud faces, WC – Co on fan blade midspan stiffeners in gas turbine engines, and

WC or Cr_3C_2 in cobalt-free matrices in the nuclear power generation industry.

4. Aluminum Alloys

The first official alloy designation was drawn up for commercially pure aluminum in 1888. Many different alloys have since been produced. During the past 20 years, substantial developmental work has been carried out in the fields of powder metallurgy, rapidly solidified alloys, and aluminum matrix composite materials.

4.1. Conventional Alloys

The basis for high-strength alloys was the work carried out in Berlin in 1906 by WILMS, in which the existence of age hardening in Al – Cu alloys was discovered. The development of high-temperature aluminum alloys depends upon precipitation hardening (see Section 3.1.2), and in the highest temperature alloys this is supplemented by dispersion hardening (see Section 3.1.3) with various high-melting intermetallics. The major precipitation-hardening systems are Al – Cu, Al – Mg – Si, and Al – Zn – Mg. The materials are produced as wrought and cast alloys. The production processes for wrought and cast aluminum and the Aluminum Association designations for alloys and tempers are discussed elsewhere (→Aluminum Alloys). Compositions of conventional aluminum alloys are listed in Table 5.

4.1.1. Wrought Alloys

Al – Cu – Mg Alloys (2XXX Series). The early work of WILMS led to the production of the alloy Duralamin, which was used for the rigid framework of Zeppelin airships; subsequent developments (e.g., 2014) have been used widely for aircraft construction. The relatively high silicon content in 2014 increases the hardening response on aging. Alloy 2024 is a development of 2014 with increased magnesium and with silicon reduced to impurity level. Both copper and magnesium give rise to precipitation hardening.

The early emphasis in aircraft construction materials was on maximizing tensile properties. The subsequent need to improve defect tolerance led to a greater importance of properties that govern behavior in the presence of cracks and other flaws, especially fracture toughness. As with most metals, toughness varies inversely with strength, and proof strength must be limited in high-strength alloys where fracture toughness requirements are essential. Crack growth is encouraged by the presence of insoluble intermetallic particles that contain silicon and iron (as an impurity); toughness can be improved by

Table 5. Composition (wt %) of aluminum alloys ∗

Alloy	Cu	Mg	Mn	Si	Fe	Ni	Ti	Zn	Sb	Zr
Duralumin	3.5	0.5	0.5							
2014	4.4	0.5	0.8	0.9	0.7					
2024	4.4	1.5	0.6	0.5	0.5					
2124	4.4	1.5	0.6	0.2	0.3					
2618	2.3	1.5		0.2	1	1	0.05			
7075	1.6	2.4		0.4	0.5			5.5

RR 350	5			0.2	0.2	1.5	0.2		0.25	0.2

∗ The balance is aluminum.

maintaining the combined level of iron and silicon below 0.5 % (Fig. 28) [48]. Alloy 2124 is essentially 2024 with a lower iron and silicon content. The requirement for a material with long-term creep capability at ca. 120 °C (e.g., for the skin of the supersonic aircraft Concorde) led to the development of 2618 which, in its earlier forged form as RR 58, was used for pistons, impellors, and compressor blades in aircraft gas turbine engines. In addition to the precipitation hardening from copper and magnesium, the nickel and iron give rise to dispersion strengthening by the intermetallic compound $FeNiAl_9$.

Figure 28. Effect of iron and silicon content on fracture toughness of Al – Cu – Mg alloys

Al – Zn – Mg – Cu Alloys (7XXX Series). World War II was largely responsible for the development of the Al – Zn – Mg – Cu alloy series, which has the greatest response to age hardening of all aluminum alloys; however, susceptibility to stress corrosion restricted the use of the strongest alloys. Control of composition (particularly the zinc – magnesium ratio) and of residual stress was found to be beneficial. Use of a duplex aging treatment to nucleate a fine dispersion of $MgZn_2$ from preexisting GP zones increased the stress corrosion resistance in alloy 7075. This alloy has been used widely in the construction of civilian and military aircraft [49]. A tougher alloy 7475 with reduced silicon and iron content is used in modern aircraft. Alloy 7075 is somewhat stronger than 2024 and RR 58 at lower temperature but has inferior temperature capability (Fig. 29). When used in sheets for aircraft skin, the 2XXX and 7XXX series of alloys are roll clad with aluminum or Al – 1 Zn to provide corrosion protection. Cladding lowers the tensile and fatigue strengths, which must be allowed for in the design.

Figure 29. Ultimate tensile strength (UTS) of conventional aluminum alloys

4.1.2. Casting Alloys

High-silicon alloys are important casting alloys because of the high fluidity caused by the Al–Si eutectic. Alloy A 332 is used for pistons in internal combustion engines, but Al–Si alloys generally do not have high-temperature capability. Alloys based on Al–Cu are better, but casting is more difficult, with potential problems in hot tearing and shrinkage porosity. Alloys have been developed with improved high-temperature properties and adequate castability; they utilize precipitation hardening and dispersion strengthening by intermetallic compounds. Y alloy has been used for diesel engine pistons; RR 50 was used for air-cooled cylinder heads of aircraft piston engines and continues to be used in gas turbines for intake and compressor casings.

Developments to further increase temperature capability resulted in RR 350. Grain refinement is achieved by the presence of titanium intermetallics. Dispersions of nickel and zirconium intermetallics increase creep strength, and addition of a small amount of antimony improves castability. The alloy is effective up to 300 °C in jet engine components (e.g., compressor casings).

4.2. Powder Alloys and Rapidly Solidified Alloys

4.2.1. Sintered Aluminum Powder

The first aluminum alloy produced by powder metallurgy techniques was probably *sintered aluminum powder* (SAP) [50]. It was produced by ball-milling aluminum powder in an 8 % oxygen atmosphere. The surface oxide layer that formed on the powder was crushed and dispersed in the aluminum matrix by extrusion, forging, or rolling after the initial pressing and sintering. The amount of oxide present in the final material depends on milling conditions. With ca. 6 % Al_2O_3, a significant level of tensile strength is maintained at a temperature close to the melting point. With up to 20 % Al_2O_3, some strength is retained above the melting point of aluminum, which implies a continuous oxide network. Despite attractive high-temperature strength (Fig. 30), the ductility at elevated temperature is poor and SAP has found relatively few applications. Its major use has been as cans for fuel elements in nuclear reactors.

4.2.2. Recent Powder Alloys

Recent interest in powder alloys was motivated by the need for increased strength. The major advantages are that dispersed particles (e.g., the Al_2O_3 in SAP) can be incorporated and rapid solidification rates can be achieved because of the small volume of material that solidifies to produce the individual powder particles. This results in metastable alloys that cannot be produced by conventional cast ingot methods. In principle, alloying limits can be increased by enhanced supersaturation, thereby providing greater precipitation hardening and introducing nonequilibrium metastable phases [51]. Modified versions of alloy 7075 have been produced in which the zinc content was increased and cobalt, usually an insoluble element, was added [52]. Some mechanical properties improved, but fatigue crack growth rates were higher; this had also been observed with some alloys of conventional composition made by powder metallurgy techniques. The result has been a cautious approach to the application of powder aluminum technology. Another consideration is that metal working temperatures must be restricted if the advantages of the metastable alloy compositions are to be retained.

The mechanical alloying process has been applied to aluminum alloys [53]. Oxide and carbide dispersions were introduced in small amounts

(2 – 4 vol %), but because of the fine dispersion, the effect on strength was somewhat greater than with the coarser particles typically found in SAP. Mechanical working of the material is important in property development. The alloy IN 9052 (Al – 4 Mg – 1.1 C – 0.8 O_2) is reported to combine the corrosion resistance of the Al – Mg series with the strength of the 2XXX series.

Techniques other than powder technology have been used to achieve the rapid solidification that allows the use of novel alloy compositions (e.g., Al – Fe and Al – Cr alloys in Fig. 30). These include splat cooling (RST 2 alloy), centrifugal atomization (RST 1), and vapor deposition (RST 3) followed by consolidation and mechanical working. Strengthening is achieved by supersaturating the aluminum lattice with iron and chromium and incorporating a dispersion of 20 – 30 vol % fine intermetallic particles such as Al_6Fe and Al_7Cr. Compared with conventional alloying elements (e.g., copper and magnesium), transition elements (e.g., iron and chromium) have low solubilities and low diffusion coefficients, which are beneficial (Table 6) [54]. The creep strength data in Figure 31 [55] show the potential of this technology to improve temperature capability over conventional alloys.

Table 6. Solubility and diffusion coefficients of elements in aluminum

Solute	Maximum solid solubility, wt %	Diffusion coefficient D_0, m^2/s
Copper	5.7	1.5×10^{-5}
Magnesium	17.4	1.2×10^{-5}
Iron	0.05	4.1×10^{-13}
Chromium	0.72	3.0×10^{-11}

Figure 31. Creep strength (0.2 % strain in 100 h) of rapidly solidified aluminum alloys

4.3. Metal-Matrix Composites

(→Metal-Matrix Composites)

Aluminum matrix composites have been developed considerably since the 1960s. The aluminum matrix can be reinforced with particulate materials (e.g., silicon carbide grit), whiskers, or continuous fibers (e.g., alumina, silicon carbide, or boron coated with silicon carbide). Manufacturing techniques depend on the type of reinforcement: squeeze casting [56] and powder technology are used for discontinuous reinforcements of ca. 20 – 30 vol %, and plasma spraying, liquid metal infiltration, and diffusion bonding techniques using metal foil are employed for continuous reinforcements.

The superior properties of the reinforcement result in benefits such as a considerable increase in strength and stiffness, together with the ability to control thermal expansion (Table 7). The highest strength and stiffness are achieved by using continuous reinforcement such as boron or silicon carbide fibers (Fig. 32 area a; see next page), whereas lesser improvements are achieved by using particle reinforcement (Fig. 32 area b) [51]. The reinforced particulate material has nearly isotropic properties, whereas continuous reinforcement produces highly anisotropic properties.

Table 7. Comparison of properties of potential reinforcements with a typical aluminum alloy

Material	Modulus of elasticity, GPa	Ultimate tensile strength (UTS), MPa
Aluminum alloy 2024	74	450
SiC monofilament	400	3500
Nicalon fiber	200	2500

The upper temperature limit for aluminum matrix composites depends on reinforcement type and orientation. Particulate reinforcement can increase temperature capability to some extent, but the best results are obtained with continuous fibers aligned in the direction of reinforcement (Fig. 30). Much of this benefit is lost in the direction perpendicular to the fiber; the use of two-directional reinforcement to reduce anisotropy reduces the strength relative to the undirectional value.

Figure 32. Improvement in properties due to fiber (a) and particulate (b) reinforcement of aluminum alloys

Property improvements are expensive due to the high cost of most reinforcements, but high-volume production could result in significant cost reduction. The cost is likely to result in the use of aluminum matrix composites where performance is critical and economics are secondary. Typical applications could include satellite and space structures; missile, aircraft, gas, and turbine compressor components; and reciprocating engine components (e.g., pistons and connecting rods).

5. Titanium Alloys (→Titanium, Titanium Alloys, and Titanium Compounds)

Titanium alloys date back to the early 1950s. The extraction and melting of titanium present unique problems caused by the high reactivity of molten titanium and its ability to reduce the refractory oxides used for traditional melting crucibles. Consumable electrode melting of titanium in the form of compacted sponge or granules blended with the alloying additions is used to produce ingots [58]. Conventional casting is impossible, and skull melting into rammed graphite molds has been used.

The two properties that motivated the development of titanium alloys are their low density and high corrosion resistance. The density of titanium falls between those of aluminum and iron, and the high specific strength of titanium alloys has resulted in rapid growth in their use in aerospace. Their excellent corrosion resistance is due to the formation of a thin protective layer of TiO_2, which has led to their use in general engineering applications where resistance to salt water and other liquids is necessary.

5.1. Metallurgy

Unalloyed titanium exists in two forms: a close-packed hexagonal α phase stable to up to 882 °C, and a body-centered cubic β phase stable from 882 °C to the melting point (1668 °C). The α phase has a higher inherent temperature capability. The use of heat treatment to develop the properties of titanium alloys is based on the controlled transformation of the β to the α phase. The extent to which the transformation can be controlled is governed by the cooling rate after heat treatment and by alloy composition. Alloying elements are of three types:

1) oxygen, nitrogen, carbon, and aluminum are strong α stabilizers,
2) molybdenum, vanadium, and niobium stabilize the β phase; and
3) tin and zirconium are largely neutral in terms of phase stabilization and very soluble in both α and β phases.

Compound formation occurs with addition of copper and silicon. The Ti – Cu system exhibits age hardening with precipitation of the Ti_2Cu phase, whereas silicon forms the compound Ti_5Si_3 and increases creep resistance significantly [59].

Three basic types of titanium alloys exist: α, $\alpha + \beta$, and β (Fig. 33). A fourth type, near-α alloys is usually included in alloy classifications.

α Alloys. The α alloys contain α-stabilizing alloying additions, the most important are the commercially pure (CP) titanium grades. Oxygen is used as a strengthening element to provide several grades of CP titanium with various combinations of strength and ease of fabrication (Table 8). The alloy Ti 115 is soft and ductile, and is used when maximum formability is required, particularly after welding. The Ti – 2.5 % Cu precipitation-hardening alloy (IMI 230) is as formable and weldable as CP titanium but has better mechanical properties and can be used up to 350 °C. Normal heat treatment is by solution

Figure 33. Typical titanium alloy microstructures
A) IMI 685; B, C) Ti 6 – 4; D, E) IMI 550

at 800 °C, followed by age hardening at 400 – 415 °C.

Table 8. Properties of commercially pure titanium

Alloy	Oxygen, %	Minimum 0.2 % PS, MPa	Elongation, %
ICI titanium 115	0.07	200	30
130	0.20	310	20
150	0.30	430	18

($\alpha + \beta$) Alloys. The early ($\alpha + \beta$) alloys (e.g., IMI 315) were forged and annealed at a temperature in the ($\alpha + \beta$) phase field to produce a microstructure of fine, equiaxial α grains with discrete β particles in the grain boundaries; Ti 6 – 4 was first used in this condition (Fig. 33B). However, fracture toughness was subsequently found to improve when two-stage heat treatment was used to produce a microstructure with a significant proportion of coarse transformed β phase (Fig. 33C) [60].

This structure is used in Ti 6 – 4 in compressor disks. The strongly β-stabilized alloys (e.g., IMI 550, Fig. 33D) retain more than the equilibrium amount of β phase on cooling from heat treatment in the $(\alpha + \beta)$ phase field. Subsequent heat treatment at a lower temperature precipitates a fine acicular form of α phase within the β phase (Fig. 33E) and increases strength. The low-pressure compressor rotor of the Olympus 593 engine, which powers the Concorde, uses IMI 550 disks and TI 6 – 4 blades.

β Alloys. Stabilization of the β phase down to ambient temperature requires comparatively large amounts of the dense β-stabilizing elements. These alloys are, consequently, ca. 20 % denser than the α and $(\alpha + \beta)$ alloys. They have inherently poor creep strength because they possess a body-centered cubic structure, and are thus not considered high-temperature alloys.

Near-α Alloys. The need to increase creep resistance led to the development of near-α alloys. The $(\alpha + \beta)$ alloys Ti 6 – 4 and IMI 550 contain too much β phase to have adequate creep strength in the highest temperature applications. The near-α alloys are strengthened mainly by α-stabilizing elements and neutral elements, with minor amounts of β stabilizers. Early alloys such as Ti 8 – 1 – 1 and Ti 6 – 2 – 4 – 2 were $(\alpha + \beta)$ forged and heat treated, and some contained small additions of silicon to increase creep strength. The discovery that significant improvement in creep resistance could be achieved by heat treating in the β phase field and quenching to produce a microstructure consisting of the basket-weave α (Fig. 33A) led to the alloys IMI 685 and IMI 829 [58].

Compositions of the alloys discussed are given in Table 9; proof strength and creep strength are shown in Figures 34 and 35, respectively.

Figure 34. Typical 0.2 % proof strength of titanium alloys

Much activity in recent years has been devoted to the development of alloys based on titanium aluminides. Conventional titanium alloys would require some form of surface protection to prevent the formation of a brittle oxygen-containing surface α layer at a temperature higher than the current maximum capability of ca. 600 °C. Compositions based on the intermetallic compounds TiAl and Ti_3Al have good oxidation resistance and low density. The binary compositions, however, are unacceptably brittle, and research has been directed toward improving the mechanical properties by compositional modifications [61].

Table 9. Composition (wt %) of titanium alloys ∗

Alloy	Cu	Mn	Al	V	Sn	Mo	Si	Zr	Nb

∗ The balance is titanium.

Figure 35. Typical creep strength (0.1 % strain in 100 h) for various titanium alloys

5.2. Uses

The aerospace industry has provided the prime motivation for the development of titanium alloys. In the United States, all titanium alloys produced in 1955 were used in aerospace, with over 60 % being used in jet engine compressors. In 1973, the bulk of production was still directed toward aerospace, but ca. 20 % was used by the chemical and general engineering industries [62].

Figure 36. Specific strength comparison of typical jet engine materials

The benefits of titanium derive from its superior strength – density ratio relative to high-temperature steels. The newer high-temperature titanium alloys have similar advantages over nickel superalloys at the compressor temperatures of modern jet engines (Fig. 36). Replacement of steel with Ti 6 – 4 and design changes (made possible in large measure by the use of titanium, including an additional two-stage front fan), resulted in 42 % increase in takeoff thrust, 13 % reduction in fuel consumption, and 18 % reduction in weight in one jet engine development in 1960 [63].

Table 10. Temperature capability of titanium alloys

Alloy	Year available	Approximate temperature capability, °C
Ti 6 – 4	1950	350
IMI 550	1956	400
Ti 8 – 1 – 1	1958	420
Ti 6 – 2 – 4 – 2	1966	475
IMI 685	1967	550
IMI 829	1977	600

Titanium use now accounts for ca. 30 % of the dry weight of current engines. Temperature capability has increased ca. 250 °C relative to the first Ti 6 – 4 alloy (Table 10) [64]. Typical applications include compressor disks, blades, and casings. Some of these applications require weldability, but not all titanium alloys can be welded. The Ti 6 – 4 alloy and some of the more recent near-α alloys can be welded, but the stronger ($\alpha + \beta$) alloys such as Ti 6 – 2 – 4 – 6 cannot. Component reliability is vital in many applications (e.g., compressor disks), and such properties as fracture toughness and crack prop-

agation rate are important design factors. To optimize these properties, the overall forging and heat treatment process is controlled to develop the microstructure [65].

Many airframe components, (e.g., wings and fuselage) are subject to bending loads so that a considerable proportion of the structure is designed in compression. Titanium alloys have a higher compression panel efficiency than other materials except at low compression load intensities (Fig. 37) [66]. Modern military aircraft contain more titanium than earlier aircraft did. The F 14 airframe contains 25 % titanium and the F 15 up to 34 %, compared with 9 % in the earlier F 4. The Boeing 747 airframe uses ca. 14 t of mill-shape titanium [62].

Figure 37. Panel buckling characteristics for steel, aluminum, and titanium alloys

The chemical and general engineering industries use mainly commercially pure titanium because of its excellent corrosion resistance. This property is increasingly important in the chemical, petrochemical, and process engineering industries where titanium is used in tubing for condensers, steam turbines for nuclear- and fossil fuel-fired power plants, and heat exchangers in onshore oil refineries where the corrosion potential of poor-quality brackish or estuary cooling water must be accommodated with temperatures up to 350 °C [62].

6. Steels (→Steel)

High-temperature steels are defined as those which contain alloying elements to improve properties for high-temperature. These elements include chromium, nickel, and aluminum for corrosion and oxidation resistance and relatively small amounts of molybdenum, vanadium, titanium, and niobium for strength. The two basic types of steel are ferritic – martensitic and austenitic, both have high-strength and high-corrosion resistance versions. *Austenitic steels* have a face-centered cubic (fcc) structure and thus an inherent advantage in temperature capability over the body-centered cubic (bcc) *ferritic/martensitic steels,* although the latter have higher proof and tensile strength at low temperature.

6.1. Low-Alloy Steels

Carbon steels are used widely for superheater tubes and steam pipes operating up to ca. 450 °C, but above this temperature low-alloy steels are required. Solid-solution strengthening is developed essentially by addition of small amounts of molybdenum [67]. The major strengthening effect in low-alloy steels, however, is precipitation hardening with coherent carbide precipitates. The intermediate form of precipitate is usually coherent with the matrix, whereas the equilibrium precipitate, which forms above 650 °C, is not. The cubic carbides V_4C_3 and NbC produce the highest creep strength; Mo_2C is more effective than Cr_7C_3.

Several types of commercial low-alloy steel can be found.

Molybdenum Steel. Molybdenum steel is the simplest steel in high-temperature service. It contains 0.5 % molybdenum and is not normally used above 480 °C. It is used in the normalized condition, e.g., with a ferrite – pearlite microstructure that contains an M_3C carbide. This carbide has a low solubility for molybdenum; thus, solid-solution strengthening is the major factor in developing creep resistance. This steel has been used extensively for superheater tubing and other boiler components for steam turbines.

Chromium – Molybdenum Steel. Molybdenum steels suffer from low creep ductility, and a 1 Cr – 0.5 Mo steel has superior creep strength with improved ductility. It is also used in the normalized condition. The addition of chromium eliminates the danger of graphitization that can occur in molybdenum steel, and thus Cr – Mo steels can be used up to 520 °C.

Vanadium-Containing Steels. Further improvement in creep strength can be obtained by addition of a small amount of vanadium (Fig. 38). A 1 Cr – 0.5 Mo – 0.2 V steel is normalized and then tempered at 650 °C to develop the V_4C_3 precipitate. This precipitate does not coarsen rapidly below 600 °C, and the steel can be used up to 580 °C. It has been employed in steam turbine rotors and also used for turbine disks in some early jet engines [68]. Large section disks require steel with better hardenability and a 3 Cr – 0.5 Mo – 0.5 W – 0.7 V steel has been used in such applications, as well as in jet engine disks operating at higher stress than was possible with the 1 Cr – Mo – V material.

Figure 38. Creep properties (rupture in 1000 h) for various high-temperature steels

6.2. Martensitic 12 % Chromium Steels

The need to increase jet engine component life at the temperature at which the strongest low-alloy steels were operating led to the development of the high-strength martensitic 12 % chromium steels. Steels containing 12 % chromium, sometimes with small additions of molybdenum and vanadium had been used for many years for steam turbine blades because of their high corrosion resistance, but their strength was not equal to that of the low-alloy steels. Addition of further chromium to the 3 Cr – Mo – W – V steel causes an unacceptable loss of creep resistance (Fig. 39) because it results in the replacement of V_4C_3 with the less effective strengthener Cr_7C_3 [69]. The 12 % chromium steels can be strengthened by an M_2X precipitate, however, where X is a combination of carbon and nitrogen [27]; M_2X is stabilized by molybdenum, vanadium, niobium, and nitrogen.

Figure 39. Effect of chromium content on creep strength (strain at 125 MPa, 600 °C) of a low-alloy steel base composition

Molybdenum, vanadium, niobium are ferrite-stabilizing elements and must be balanced by austenite stabilizing elements (e.g., cobalt, nickel, and nitrogen) to maintain the required properties. High-temperature heat treatment at ca. 1150 °C is needed to fully dissolve the alloying elements that form the M_2X precipitate on subsequent tempering at 600 – 650 °C. The creep properties of FV 535 are illustrated in Figure 38. Materials of this type were used for disks in early jet engines although they were superseded by nickel superalloys in subsequent engine designs.

The efficiency of steam plant in electric power generation is increased by operation at higher steam temperatures and pressures. Early subcritical boilers used low-alloy steels, but supercritical plant required higher temperature steels. FV535 was found to be unsuitable for

thick-section components because of chemical segregation. Developments based on 9 % chromium steels used in the petrochemical industry have resulted in steels such as P91 [70], which have allowed operation at temperatures around 600 °C, some 50 °C higher than is possible with low-alloy steels.

6.3. Ferritic Heat-Resistant Materials

According to the definition of steels as iron–carbon alloys with other alloying additions, ferritic heat-resistant materials are not strictly steels and are sometimes referred to as *stainless irons*. Alloys of iron and chromium with <0.05 % carbon are ferritic and cannot be strengthened by heat treatment. They have been used in applications requiring oxidation resistance, but little strength. The oxidation resistance increases with chromium content (Fig. 40) [71] and can be increased further by addition of aluminum and small amounts of rare-earth elements (e.g., yttrium), which reduce oxide spallation by an oxide pegging mechanism. Materials of this type are used as resistance heating elements for furnaces from laboratory- to production-scale size in the ceramic, glass, engineering, and metal-processing industries. Maximum temperature capability depends on composition as illustrated in Table 11.

Table 11. Temperature capability of ferritic, heat-resistant materials

Temperature limit for continuous use, °C	Composition, wt %		
	Cr	Al	Y
1050	15	4.5	
1300	16	5	0.3
1350	22	5	

Figure 40. Influence of chromium and nickel on cyclic oxidation resistance of steel

6.4. Corrosion-Resistant Austenitic Steels

The ferritic high-chromium steels have low strength at high temperature, but the addition of sufficient nickel to stabilize the face-centered cubic austenitic structure significantly increases the strength (Fig. 41) with little effect on oxidation resistance (Fig. 40). Steels with higher chromium and nickel content are more suitable than the 18 – 8 types for high-temperature service because of their superior high-temperature strength, oxidation, and corrosion resistance (Table 12).

Chromium carbides precipitate in the grain boundaries when 18 – 8 steels are heated at 500 – 850 °C, producing local chromium depletion that leads to intergranular corrosion when the alloy is subsequently subjected to corrosive environments. Addition of small amounts of titanium or niobium, in quantities related to the carbon content, prevents this problem by the for-

Table 12. Temperature capability and typical uses of corrosion-resistant austenitic steels

Steel	Maximum temperature in oxidizing environment, °C	Typical applications
18 Cr – 8 Ni	850	heat exchanger tubes, exhaust manifolds
24 Cr – 12 Ni	1050	furnace components
25 Cr – 20 Ni	1150	petrochemical equipment, nuclear fuel element cans

Figure 41. Creep strength (1 % strain in 10 000 h) of corrosion-resistant austenitic steels

mation of stable TiC or NbC. To improve general corrosion resistance, ca. 2 % molybdenum is often added to austenitic steels; this type of steel has been used for many years in superheater tubes for land boilers and reactor heat exchangers. Embrittlement due to precipitation of the σ phase, an iron – chromium-based composition, can be experienced in some steels on long-term exposure at 750 – 850 °C; σ phase formation is accentuated by ferrite-stabilizing elements such as molybdenum and silicon. Selection of steels with composition appropriate for the particular service environment is, therefore, important.

Although nickel has little effect on oxidation resistance, it provides a major improvement in corrosion resistance, particularly in relatively low oxidation potential environments. Steels with high nickel content are required for resistance to carburization (Fig. 42) (e.g., in petrochemical processing to produce ethylene by thermal cracking of hydrocarbon – steam mixtures at 1000 – 1100 °C). Low carbon absorption is essential to minimize the stress gradient, which can result in failure when added to the operating stress [72].

6.5. Controlled-Transformation Stainless Steels

Some of the 12 % chromium martensitic steels are available in sheet form (e.g., Jethete M 152 and FV 607), but their formability is somewhat limited. The controlled-transformation stainless steels AM 350, FV 520, and 17 – 7 PH combine the excellent formability of the austenitic steels with strength approaching that of the 12 % chromium martensitic steels. Compositions are such that the transformation of austenite to martensite occurs below room temperature. Thus the steel in the solution-treated condition is austenitic, and formability and weldability are good. Strengthening is then achieved by transforming the structure to martensite either by refrigeration close to the martensite formation temperature (M_f) or by heat treatment at 450 – 700 °C. This heat treatment precipitates carbides and raises the martensite transformation range above room temperature. Secondary hardening can be achieved by small amounts of copper and aluminum. Use includes applications where strength and corrosion resistance are required, for example, in jet engine fabrications and in certain parts of the skin of high-speed missiles and aircraft operating up to 550 °C.

6.6. High-Strength Austenitic Steels

High-strength austenitic steels are strengthened either by complex carbides or by intermetallic compounds. The material used by WHITTLE for the turbine blades and disk of his WI engine in 1937 was Stayblade, a simple austenitic stainless steel developed for steam turbine uses. This was found to have inadequate creep strength in the disk rim and was replaced by G 18 B, a carbide-strengthened austenitic steel that had been used for the exhaust valves of reciprocating aircraft engines. Although G 18 B was found to have inadequate proof strength in the disk bore, warm working at 650 – 900 °C significantly increased proof and creep strength (Fig. 38) [73]. A similar concept was used in the United States with 16 – 25 – 6, a 16 Cr – 25 Ni – 6 Mo steel. The materials strengthened by intermetallic compounds are based on Tinidur, which is precipitation hardened with an $(Fe,Ni)_3Ti$ precipitate; A 286 steel was developed from Tinidur. In addition to the

major alloying elements, A 286 contains a small amount of molybdenum to control the morphology of the precipitate and thus improve notch ductility at elevated temperature; a small amount of aluminum and boron improves hot workability. Together with a similar steel Discaloy, A 286 was used in early jet engine disks and is still employed for turbine disks in industrial gas turbines.

Compositions of the steels discussed in this section are given in Table 13.

7. Nickel Alloys (→Nickel Alloys)

Nickel – chromium alloys date back to the early 1900s when their high-temperature oxidation resistance was first recognized. The development of nickel alloys has had two objectives: (1) increased oxidation and corrosion resistance, with strength improvement being of secondary importance, and (2) increase in strength and temperature capability, which has been motivated almost entirely by the gas turbine. This has been so successful that nickel superalloys can be used in stressed applications up to $0.8\,T_{\mathrm{m}}$, a greater proportion of their melting temperature than any other alloy system.

7.1. Metallurgy

The alloying additions that may be present in high-temperature nickel alloys are shown in Figure 43. The heights of the major alloying element blocks give some indication of the amount that may be present, and their main functions are indicated [74]. Trace elements can have a significant influence on properties and behavior; beneficial trace elements are cross-hatched, and detrimental trace elements are shaded horizontally.

The range of microstructures that can exist in nickel alloys is shown in Figure 44. Chromium and aluminum are sufficiently soluble in the nickel matrix to allow protective scales of either Cr_2O_3 or Al_2O_3 to be formed, depending on composition. The two oxide formers have a powerful synergistic effect; in ternary alloys, chromium significantly reduces the amount of aluminum required to form Al_2O_3 compared with that required in binary Ni – Al alloys (Fig. 45) [75]. To some extent, temperature and time influence the oxides that are formed, and the boundaries are thus shown as dashed lines.

Solid-solution, precipitation, and dispersion strengthening are all important strengthening mechanisms. Precipitation strengthening involves the γ' phase based on Ni_3Al. Other alloying elements can be substituted for nickel and aluminum, modify the characteristics of γ', and thus modify alloy behavior. Cobalt can replace nickel; titanium, niobium, tantalum, and hafnium can be substituted for aluminum; and molybdenum, chromium, and iron can replace both nickel and aluminum. Too little aluminum results in a metastable γ', which transforms to a weaker platelike η phase (Ni_3Ti) if the titanium –aluminum ratio exceeds a critical value, or to Ni_3Nb if the alloy contains more than 4 % niobium. The influence of the $\gamma - \gamma'$ mismatch, size, and volume fraction of γ' precipitate is discussed in Section 3.1.2.

Figure 43. Elements in nickel superalloys and their principal effects (see text for further description)

Figure 44. Schematic microstructure of nickel superalloys

Figure 45. Effects of chromium and aluminum on oxides formed on nickel superalloys

The main types of carbide are $M_{23}C_6$ and MC. The $M_{23}C_6$ carbides tend to predominate in high-chromium alloys. They play a significant role in inhibiting grain boundary sliding when they exist as discrete particles in the boundaries. The MC carbides are very stable and usually form during solidification. They form in alloys containing significant amounts of hafnium, tantalum, and niobium, and can react with the γ matrix to produce $M_{23}C_6$ and γ'. This is an important reaction because it surrounds the grain boundary carbides with a relatively ductile, creep-resistant layer.

Table 14. Composition, temperature capability, and typical uses of electric resistance heating materials

Alloy	Composition, wt % *				Maximum operating temperature, °C	Main application
	Cr	Fe	Si	Al		
Brightray B	16	24			950	low duty domestic heating
Brightray S	20				1150	larger section furnace resistors
Brightray C	20		1.5		1150	frequent and wide temperature variations e.g., domestic cookers, radiant fires
Brightray H	20			3.5	1250	furnace resistors

* The balance is nickel.

In addition to the γ' and carbide phases, which are controlled to develop the beneficial properties of nickel alloys, other phases form in some alloys on long-term exposure at 650–925 °C and have serious adverse effects on toughness and creep strength. The most common of these is the σ phase. It has a platelike morphology and its general formula is $(CrMo)_x(NiCo)_y$.

7.2. Oxidation-Resistant Nickel Alloys

After the excellent oxidation resistance of Ni–Cr alloys had been recognized, the Ni–20 % Cr alloy was found to be particularly suitable for electric resistance heating elements. This type of alloy remains one of the most important materials used in this application, although significant improvements have been made. One modification incorporates small amounts of reactive elements such as calcium, cerium, zirconium, and silicon in Brightray C. These are effective in increasing lifetime in thermal cycling by improving the adhesion of the protective oxide. The compositions and primary applications of some alloys are listed in Table 14.

Since the early development of the electric resistor alloys, a parallel development of general corrosion-resistant nickel alloys has occurred (Table 15). The material that has become the traditional alloy for general industrial furnace parts (e.g., retorts and heat treatment equipment) is Inconel 600. It is resistant to attack by N_2–H_2 mixtures and NH_3, and is a standard material for ammonia cracking plants and nitriding equipment. Incoloy DS is a higher iron version containing silicon. It is particularly resistant to carburization and alternating carburizing–oxidizing environments, and is used extensively in industry under such conditions. It was originally developed for wire-woven furnace conveyor belts but has been used increasingly in other equipment. Inconel 601 is a higher chromium alloy containing aluminum with improved oxidation resistance and strength (Fig. 46). In addition to general furnace equipment, it is also

Figure 46. Strength (A) and oxidation resistance (B) of nickel alloys

7.3. Nickel Superalloys

Nickel superalloys are alloys developed for elevated temperature service in which severe mechanical stress is encountered and high surface stability is often required. They have been developed to meet gas turbine requirements, with specific applications in mind; thus, the major gas turbine components are used as the basis for this discussion. The development of nickel superalloys and their associated manufacturing processes can be divided into four categories: *turbine rotor blade, turbine stator blade, turbine disk,* and *sheet materials*. When first introduced into turbine components, their properties were so superior to those of their predecessors that alloy development alone was sufficient to meet the design needs, with relatively little contribution from the manufacturing process other than to produce the required shape. At a later stage in component development, the manufacturing process became a key part of the material technology because processing made a major contribution to formation of the required microstructure. In more recent developments (e.g., directional solidification), the manufacturing process makes the primary contribution, with material composition being of secondary importance. These trends are evident in the four major gas turbine components discussed in the following sections.

7.3.1. Turbine Rotor Blade Materials

The high-pressure turbine rotor blade operates under the most arduous conditions of temperature and stress of any component in the jet engine; it experiences peak temperatures in excess of 1000 °C, rapid temperature transients at various points in the flight cycle, high direct stress from rotational speeds exceeding 10 000 rpm, and a highly oxidizing environment. The first blades were die forged and superalloys used for blade applications have progressively developed in a process-controlled sequence (Fig. 47) [76]. The volume fraction of γ' precipitate was progressively increased from that in Nimonic 80 to increase creep strength. Cobalt was added, initially in Nimonic 90, to raise the γ' solvus temperature, and solid-solution strengthening was increased by the addition of molybdenum in Waspaloy, Nimonic 105, and later alloys. Alloy content higher than that of Nimonic 115 resulted in serious forging difficulties and therefore Nimonic 115 represents the strongest wrought blade alloy.

Figure 47. Temperature capability of gas turbine blade alloys based on rupture in 1000 h under stress of 150 MPa
a) Wrought; b) Conventionally cast; c) Directionally solidified and single crystal

Investment or lost-wax casting has existed for ca. 2000 years but was adopted for commercial applications only in the early 1900s. It was first applied in the manufacture of supercharger buckets using the cobalt-base alloy HS 21 in the piston engines of U.S. military aircraft during the 1940s. The reactivity of the aluminum and titanium in nickel superalloys caused problems in air melting and casting; the use of casting for the manufacture of blades in the strongest superalloys was made possible by the development of vacuum melting and casting techniques in the late 1950s [77]. Inco 713 C was one of the first alloys to be vacuum cast and is widely used. As with wrought alloys, the demand for stronger cast alloys was initially met

by increasing the aluminum and titanium content. This led to the development of IN 100, whose microstructure contains 60 – 70 vol % of γ'. Early compositions of IN 100 were found to be metallurgically unstable, with σ phase forming on long-term exposure at intermediate temperatures (650 – 900 °C). This problem was avoided by modifying the composition. Because further increase in the amount of γ' phase to increase the strength was impractical, later alloys such as B 1900 tended to have (1) higher levels of molybdenum and tantalum to increase solid-solution strengthening, and (2) reduced titanium, what was found to improve castability. Stronger alloys (e.g., Mar M 002) were subsequently developed in which molybdenum was replaced by tungsten and hafnium was added to ensure adequate creep ductility at intermediate temperature [78]. Trace elements in quantities ranging from <1 ppm up to ca. 2000 ppm, depending on the element, can have a major effect on creep properties and tensile ductility. As shown in Figure 43, elements such as sulfur, bismuth, lead, and silver can be detrimental, whereas carbon, boron, zirconium, and magnesium have specific beneficial effects [74]. The changes in composition necessary to achieve higher creep strength have relatively little effect on high-temperature oxidation resistance but produce a marked deterioration in hot corrosion resistance (Fig. 48). Developments [79] include alloys with strengths equivalent to the earlier cast alloys such as Inco 713 C, but with improved corrosion resistance. Both IN 738 and IN 939 are such alloys; they have a higher chromium content, higher titanium – aluminum ratio, and modified refractory metal content compared to the less corrosion-resistant alloys. They are employed in industrial turbines.

Figure 48. Relation between temperature capability and hot corrosion resistance for various nickel superalloys
The material temperature capability is based on rupture in 100 h under stress of 110 MPa.

Figure 49. Contributions of material development and blade cooling to turbine entry temperature in aircraft gas turbines
a) Uncooled blades; b) Cooled blades

Since the inception of the jet engine, the need for higher turbine operating temperatures to increase the thrust developed by the engine has continued. In the early years, material development was responsible for the increase in turbine entry temperature (TET) (Fig. 49). In the 1960s, internally air-cooled turbine blades were introduced and blade cooling has played a major role in allowing increased operating temperature. The first cooled blade was forged from a drilled preform to produce a relatively simple three-hole blade (Fig. 50A). More complex and efficient cooling hole geometries can be produced in cast blades (Fig. 50B), and the latest designs feature film cooling; cooling air is exhausted through a multiplicity of small holes to form a film of relatively cool air on the surface of the blade, thereby shielding it to some extent from the hot gas stream.

Figure 50. Cooling configurations in Conway (A) and RB 211 (B) high-pressure turbine blades

The technique of directional solidification (DS) was applied to the production of turbine blades in the 1970s in alloys such as Mar M 002 and M 200 DS. Creep failure in conventionally cast blades is initiated at grain boundaries normal to the major direct stress, so that aligning grains from blade root to tip (Fig. 51) eliminates transverse grain boundaries and thus increases the creep life of the blade. To produce the directional grain structure, a macroscopically planar liquid – solid interface must be maintained in the mold perpendicular to the solidification direction; this is achieved by removing heat from the molten metal in a direction parallel to that of the desired growth. Current production processes (Fig. 52) use controlled mold withdrawal from furnaces in which the mold and metal within it have been heated to a temperature in excess of the liquidus [80]. Castings with cooling passages of similar complexity to those of conventional castings can be produced. The absence of transverse grain boundaries is a factor in the increased life of DS blades, but the major benefit arises because the [100] crystal growth direction is also the direction of lowest Young's modulus. This produces major reductions in the thermal stress from temperature gradients in the blade during service. The DS technology has been extended by relatively simple process and alloy composition modifications to produce castings consisting of a single crystal (e.g., in alloys such as SRR 99 and PWA 1480). The major process modification is the incorporation of either a geometric constriction crystal selection device, which eliminates all but one of the grains growing into it, or a seed crystal, which nucleates one grain of crystal orientation like that of the seed.

Figure 51. Directionally solidified turbine blade

Alloy composition modification involves the elimination of elements such as carbon, boron, zirconium, and hafnium, which normally provide grain boundary strengthening in polycrystalline castings. Elimination of these elements increases the solidus temperature of the alloy, allowing the use of higher temperature solution heat treatment. This leads to reduced chemical segregation, a more uniform distribution of the γ' precipitate, and consequent increased temperature capability. Such blades were introduced into commercial jet engines in the 1980s. It is essential to control the crystallographic orientation of the blades produced, and computerized real-time techniques are used [81]. The latest alloys used for single-crystal blades, such as CMSX 4, have significantly higher temperature capability than the first-generation alloys. They contain additions of rhenium, which contributes to the improved strength [82].

Figure 52. Rolls-Royce directional solidification furnace

Other developmental materials that use directional solidification techniques have not been commercialized. Directionally solidified eutectics (DSE) have been referred to as in situ composites because the reinforcing phase is aligned during the solidification process. Several different DSE materials have been developed [83], and the reinforcing phases are of two types: carbide in NiTaC materials and intermetallic in $\gamma-\gamma'-\alpha$ materials. Reinforcement is inevitably undirectional, which leads to a pronounced strength anisotropy, with transverse strength being much lower than longitudinal strength (Fig. 53). This problem has been addressed (e.g., Nitac 116 A), but cost has prevented the commercialization of DSE. The cost is high because the solidification rates necessary to develop the aligned microstructure are some two orders of magnitude slower than for DS superalloys.

Figure 53. Creep strength anisotropy in directionally solidified eutectics (DSE) based on rupture in 1000 h

Turbine rotor blade material compositions are given in Table 16.

7.3.2. Turbine Stator Blade Materials

Turbine stator blades operate at higher temperatures than rotor blades but, being stationary components, experience essentially only thermal stress. Strength requirements are thus less severe than for rotor blades. Early stator blade materials were the cobalt-based alloys HS 21

∗ All alloys contain carbon, boron, and zirconium, except the two single-crystal alloys SRR 99 and PWA 1480. Wrought alloys usually contain 0.05 – 0.10 % carbon, 0.005 % boron, and 0.05 – 0.10 % zirconium. Cast alloys generally contain 0.10 – 0.15 % carbon, 0.01 – 0.015 % boron, and 0.05 – 0.10 % zirconium.
∗∗ bal = balance.

and HS 31 used for cast supercharger buckets in piston engines. These materials have a high chromium content (28 and 25 %, respectively) to develop good oxidation resistance. Cobalt alloys do not have a precipitation-hardening mechanism comparable to that of nickel superalloys. They have higher melting temperatures than nickel superalloys, however, and superior creep strength and thermal fatigue resistance at very high temperature. The major strengthening mechanisms are solid-solution strengthening by molybdenum and tungsten, and strengthening by carbide precipitation [84]. Nickel superalloys have been used increasingly in recent years as strength requirements in highly cooled stator blades become more important.

The dispersion-strengthened material MA 754 was used in one recent engine type because of the benefit of strength at very high temperature (Fig. 54). The first practical application of dispersion strengthening in superalloys was TD Nickel (nickel with 2 % ThO_2) in the early 1960s for some combustion chamber components, where the relatively high thermal conductivity of TD Nickel was its major advantage. Poor oxidation resistance was addressed by the addition of 20 % chromium in TD Nichrome. These TD materials were produced by selective hydrogen reduction processes [85]. Mixing of thorium dioxide sols with nickel-containing solutions ensured good dispersion, and subsequent reduction of the metallic oxides after drying pro-

duced fine composite Ni – ThO_2 powder, which was then compacted, extruded, and rolled to develop its strength. The γ'-forming elements aluminum and titanium could not be incorporated because their oxides are not reduced by hydrogen. Mechanical alloying was developed to provide this capability [86]. It is essentially a dry, high-energy, ball-milling process in which particles of elemental or prealloyed powder are continually welded together and broken up until a homogeneous mixture of the constituent powder particles and dispersoid is produced. Consolidation and thermomechanical processing yield the final product. This process has produced mechanical alloy (MA) 754, which contains 20 % chromium and 0.6 % Y_2O_3; MA 6000, a γ'-containing alloy with the potential for turbine blade applications; and MA 956, a potential combuster material discussed in Section 7.3.4.

Compositions of stator blade materials are listed in Table 16.

7.3.3. Turbine Disk Materials

Superalloy disks were initially produced by the ingot – forged billet – die forged disk method. *Vacuum induction melting* (VIM) was used because of the reactive elements present. The chemical segregation that occurred on solidification of the relatively large ingots led to forging difficulties and the need for a *duplex melting sequence*, i.e., the remelting of VIM cast electrodes by either vacuum arc remelting (VAR) or electroslag remelting (ESR) [87] to control solidification, improve the structure, minimize segregation, and improve cleanliness. This duplex melting provided the basis for microstructural control of the disk superalloys until the late 1960s.

The materials in this period can be divided into two groups: nickel – iron-based alloys such as Incoloy 901 and IN 718, which developed from the precipitation-strengthened austenitic steel A 286, and nickel-based alloys such as Waspaloy and Astroloy, which were developed initially for turbine blade applications and were used subsequently, with modified heat treatment, for disks.

Figure 55. Properties of superalloy disk material compared to earlier austenitic steel
a) 0.1 % proof strength; b) 0.1 % creep in 100 h

When they were introduced, the superalloys exhibited such strength superiority over austenitic steels (Fig. 55) in the fully recrystallized and age-hardened condition that only relatively elementary control of microstructure was required in forging. The disks were die-forged using hammers or presses [88]. Recognition in the late 1960s that low cycle fatigue (LCF) was the major life-limiting factor led to the development of *thermomechanical processing* (TMP), an elementary form of which had been used in the earlier G 18 B and 16 – 25 – 6 austenitic steel disks. In thermomechanical processing, forging conditions and subsequent heat treatment are selected to produce a predetermined microstructure to enhance specific properties. The design of the forging sequence, including the deformation rate, the temperature at which the deformation is carried out in relation to the γ' carbide, and other

Table 17. Effect of grain size on properties of Incoloy 901

	Grain size, ASTM no.	Heat treatment * ST, °C	AGE, °C	0.2 % PS, MPa 20 °C	575 °C	LCF (0 – 850 MPa, 500 °C), cycles
Conventional forging	2	1090	775 + 705	866	752	$>10^4$
Modified forging	6	980	720 + 650	968	839	$>3\times10^4$

* ST = solution treatment; AGE = age hardening

solvus temperatures, is of crucial importance. The increase achieved in 0.1 % proof stress (PS) of Waspaloy is shown in Figure 55. The low cycle fatigue properties were initially improved by reducing grain size; the improvement in Incoloy 901 is shown in Table 17. The necessary structural control extends to the dislocation level [89], which plays a major role in determining component behavior. Homogeneous dislocation distributions (Fig. 56A) are satisfactory, whereas heterogeneous dislocation distributions with local high-density planar arrays (Fig. 56B) can result in premature component failure.

Attempts to develop higher fatigue strength by forging materials more highly alloyed than Waspaloy achieved little success because chemical segregation in the ingot made forging more difficult. Techniques such as hot die forging at 650 – 900 °C and isothermal forging with molybdenum TZM dies at 1000 – 1150 °C, compared to a conventional die temperature of 200 – 350 °C, were developed to provide improved deformation control during forging, but adequate microstructural control was not achieved.

This problem led to the introduction of a prealloyed powder technology for disk manufacture in the mid-1970s; a billet made by the compaction of atomized powder particles is much more chemically homogeneous than a cast ingot. The powder is produced in an inert atmosphere to avoid contamination, and argon atomization and the soluble hydrogen process are most commonly used [85]. The sieved powder, typically <50 µm in diameter, is placed in evacuated containers and consolidated either by extrusion to billet or by *hot isostatic pressing* (HIP) of canned powder to billet or rectilinear ultrasonic inspection shape. Final forging is via conventional press forging, hot die forging, or isothermal forging; superplastic processing has also been used. Materials such as Astroloy and Rene 95 are produced by this powder technology, and their strength shows significant improvement over earlier materials (Fig. 57, see next page). A better understanding of the optimum microstructure for improvements in low-cycle fatigue has accompanied their development. The fatigue performance of such powder superalloys (Fig. 58, see next page) is limited by small oxide inclusions that result from the melting process and are too small to be detected by nondestructive testing. Current activity is thus directed to fundamentally cleaner manufacturing process development and to materials that have even better defect tolerance. Compositions of disk materials are given in Table 16.

7.3.4. Sheet Materials for Fabricated Structures

Combustion chambers, high-temperature exhaust units, and jet pipes are examples of components fabricated primarily from sheet material. Weldability and formability are thus prime requirements, and the strength limitation thereby imposed is compatible with the strength and oxidation resistance necessary in these components.

Early gas turbines used several separate combustion chambers, whereas more recent designs are of annular construction. Nimonic 75, one of the first commercial nickel-based alloys, was used in early combustors and is still in use; Hastelloy X has similar capabilities. The need for higher strength combined with weldability has been addressed by the incorporation of aluminum and titanium in C 263 and Rene 41 (Fig. 59) in amounts sufficient to cause precipitation hardening but not high enough to prevent welding. The rate of precipitation in welded regions must be controlled to avoid cracking, and addition of molybdenum controls this in alloys such as C 263 and Rene 41. Increased strength is obtained at the expense of oxidation resistance, however, and the most recent alloys, Nimonic 86 and cobalt-based Haynes 188, are strengthened only by solid-solution strengthening; small amounts of cerium and lanthanum, respectively, are added to improve oxidation resistance.

Figure 59. Proof strength of superalloys in sheet form
a) Rene 41; b) C 263; c) Nimonic 75; d) MA 956; e) Nimonic 86

The nickel-based mechanical alloys are not available in sheet form, but an iron-based alloy, MA 956 is available as sheet. It has excellent oxidation resistance (Fig. 60) but, like other dispersion-strengthened materials, cannot be welded. It is not yet used in gas turbine engines but has been subjected to field evaluation in oil-fired boiler hardware and flame stabilizers [90].

Nickel superalloys are sometimes necessary in airframe structures; the precipitation-hardened alloy Inconel X 750 was used for a large part of the skin of the experimental X 15 rocket plane, and Inconel 600 and Rene 41 have been used for the skin of space capsules. Compositions of sheet superalloys are given in Table 16.

a) MA 956 (1150 °C); b) Nimonic 86 (1150 °C); c) Inconel 617 (1100 °C)

7.3.5. Nonaerospace Applications

The development of nickel superalloys was motivated by the gas turbine engine, but they have been used in a variety of nonaerospace applications where their unique combination of high-temperature strength and corrosion resistance are required.

Materials such as Nimonic 80, Inconel X 750, and Nimonic 90 have been used for internal combustion engine exhaust valves, which are subject to high temperature, impact, gas erosion, and corrosion. They have also been used for precombustion chambers in indirect injection diesel engines. The use of Inconel 600 and Nimonic 75 in exhaust manifolds for aircraft piston engines has been extended to the exhaust manifolds of high-performance sports cars.

Nimonic 90 has been used for high-temperature springs where conventional spring steels are limited to ca. 400 °C. Materials such as Nimonic 80 have been used for high-temperature bolts (e.g., in steam turbine flanges) because they have much greater resistance to stress relaxation than low-alloy steel.

Nickel superalloys are used widely in the metal-working industry for components such as hot forging dies, extrusion dies, and forging press tools. Nimonic 90 is reported to be three times more effective than conventional die steels in the extrusion of copper because of its higher thermal shock resistance and better wear properties [91].

8. Refractory Metals

Refractory metals vary according to the individual defining them, but all definitions include molybdenum, niobium, tantalum, and tungsten. These metals are all body-centered cubic in structure, and their density increases with increasing melting point. Molybdenum and tungsten are susceptible to loss of ductility at low temperature; the ductile – brittle transition temperature (DBTT) for recrystallized material is given in Table 18. The major strengthening mechanisms are solid-solution strengthening by other refractory metals and by interstitial elements at intermediate temperature, and dispersion strengthening at high temperature. In molybdenum, relatively small amounts of titanium and zirconium increase the strength by both solid-solution strengthening and the formation of small coherent precipitates of TiC and ZrC, which also modify the recrystallization behavior (Table 19). A fine dispersion of 0.5 – 2.0 % ThO_2 increases the strength of tungsten, whereas most niobium and tantalum alloys are strengthened by other refractory metals. The tensile properties of the most common refractory metal alloys are shown in Figure 61 (see next page).

Table 18. Properties of refractory metals

Metal	Melting point, °C	Density, g/cm³	DBTT, °C
Tungsten	3410	19.3	300
Tantalum	2996	16.6	<−196
Molybdenum	2610	10.2	0
Niobium	2415	8.56	−200

Table 19. Effect of alloying additions on recrystallization temperature of molybdenum

Alloy	Recrystallization temperature, °C
Mo – 0.02 C	1200
Mo – 0.5 Ti – 0.02 C	1350
TZM Mo – 0.5 Ti – 0.07 Zr – 0.02 C	1500

Figure 62. Comparison of oxidation of refractory metals with that of typical nickel superalloys

Refractory metals and their alloys are readily oxidized at high temperature, as shown in Figure 62. Considerable effort was made in the 1950s and 1960s to improve oxidation resistance because of the perceived potential for increasing operating temperatures in gas turbine engines. However, refractory alloys require coating protection in high-temperature oxidizing environments; most useful coatings are based on silicides [92]. Many commercial applications involve nonoxidizing atmospheres or vacuum, and coatings are then unnecessary.

Tungsten has been used in the filaments of incandescent electric lamps since the early 1900s. Its low vapor pressure and its strength at high temperature are essential properties. The filaments consist of wire 0.015 – 0.075 mm in diameter wound in the form of a fine helix with a diameter two to six times that of the wire. The filament operates at ca. 2500 °C in an atmosphere typically consisting of 93 % argon and 7 % nitrogen. To ensure high efficiency throughout the life of the lamp, the filament must remain substantially free from distortion; tight dimensional tolerances and metallurgical control are necessary to give a stable grain structure. Two techniques have been used to achieve this: (1) the production of a fine-grained structure in which further growth is inhibited by the presence of up to 1 % ThO_2 and (2) the production of a stable large-grained structure. Slow grain growth occurs in material containing ThO_2 and its use is limited to special applications where resistance to vibration is essential. The stable coarse-grained approach predominates in most applications. Addition of potassium and other dopants, together with controlled processing, results in wire with large axially aligned grains. Such a structure is resistant to further grain growth and has good high-temperature creep strength, which is essential for ensuring stability of the filament throughout its burning life [93]. Other high-temperature uses of tungsten include welding electrodes, springs, and electrical contacts. Molybdenum is used for heating elements and shields in vacuum furnaces, incandescent light bulbs to support tungsten filaments, X-ray tubes, and electronic components. The TZM alloy is used for cores and dies in die casting brass, aluminum, and steel, where its excellent thermal diffusivity and resistance to heat checking are required [94]. The elevated strength of TZM has led to

its use in extrusion and forging dies, e.g., in the isothermal forging of nickel superalloy disks for turbines.

Because of their high cost and limited availability, tantalum alloys are not likely to be used in large quantities for high-temperature applications. They are employed in specialized applications, for example, as heaters and shields in furnace hardware for the manufacture of tantalum capacitors, an application in which tungsten would lead to unacceptable contamination. Niobium alloys such as C 103 have been used for rocket components operating at 1100 – 1350 °C and for flaps in reheat systems in military jet engines. A Nb – 1 Zr alloy is used extensively in nuclear fusion reactors containing liquid metals because of its high-temperature strength and low absorption cross section for thermal neutrons.

9. Engineering Ceramics

9.1. Refractories (→Refractory Ceramics)

The earliest types of ceramics were clay-based refractories. The most common type, fireclay in the form of bricks, has been widely used in the metallurgical industry (e.g., to line blast furnaces, cupolas, heat treatment furnaces). Compositions range from 20 to 45 % Al_2O_3 and from 50 – 80 % SiO_2, with several clays being used along with other additions to reduce firing shrinkage and to increase stability. The firing temperature is ca. 1500 °C, and fired material typically contains 50 % glass, 35 % mullite, and 15 % cristobalite. The load-bearing capability of fireclay is directly related to the amount of glassy phase and its viscosity. Higher Al_2O_3 content gives better service under severe conditions. Softening temperatures usually range from 1750 to 1850 °C, depending on composition; typical creep properties of firebrick are shown in Figure 63 [95].

Magnesium oxide is strongly basic and is used in the processing of other basic materials (e.g., open hearth steel-making furnaces, Bessemer converters, and cement clinker processing). Mechanical weakness has been a limitation, but the hot strength of magnesite bricks has been increased significantly by reducing the silicate content and increasing the firing temperature.

The need to conserve heat led to the development of insulating firebricks, which reduced heat loss and allowed the use of thinner walls. The clay for insulating firebricks was made porous, commonly by mixing wood flour with the clay and firing to burn out the wood. Thermal conductivities ca. 25 % those of dense firebrick were obtained. More sophisticated techniques for producing porosity have subsequently been used.

Figure 63. Creep properties of firebrick at 1250 °C

9.2. Early Engineering Ceramics

Aluminum oxide is probably the first engineering ceramic; it has been used for spark plug insulators since the 1930s. For economic and technical reasons, 5 – 15 % SiO_2 is added to the Al_2O_3 in this application, where temperatures up to 850 °C and pressures up to 70 atm (7.0 MPa) can occur with rapid thermal fluctuations. Electric high-temperature furnaces with tungsten or molybdenum heating elements frequently use sintered Al_2O_3 electric insulators, and in these applications, Al_2O_3 can withstand temperatures up to 1850 °C for long periods. Silicon carbide, with a 1600 °C temperature capability in air, has long been used for kiln furniture and electric resistance heating elements. These elements are made from high purity α-SiC sintered at >2300 °C. Molybdenum disilicide ($MoSi_2$) is also used in resistance heating elements for operation up to 1700 °C; its oxidation resistance has led to its use as a protective coating on SiC elements.

9.3. Advanced Engineering Ceramics

The applications discussed in Sections 9.1 and 9.2 involve relatively low stress and moderate to high temperature. Rudimentary understanding of material behavior has allowed the improvement of properties such as strength and temperature capability.

During the last 25 years the use of ceramics in high-temperature applications involving significant tensile stress has increased largely because of an improved understanding of the relationship of processing, microstructure, and properties, and the consequent improved materials and manufacturing technology. Ceramics with better strength and temperature capability are now available. More significantly, progress has been made in reducing brittleness, which had been a major restriction on stress capability.

Several terms (e.g., fine ceramics and advanced ceramics) have been used to describe these new ceramics, but the most appropriate description would probably be *engineering ceramics*. Such ceramics require much greater control over the quality of the raw materials, as well as more sophisticated processing, controlled chemistry, and regulated microstructure. These materials include alumina, silicon carbide, silicon nitride, sialon, zirconia, and glass ceramics (see also →Ceramics, Advanced Structural Products; →Glass Ceramics).

9.3.1. Ceramic Processing

Many of the defects in ceramic components originate as defects in the green unsintered material; others are introduced during processing, shaping, densification, or final machining. Total process control from starting powders to finish grinding is, thus, crucial in the fabrication of satisfactory ceramic components.

Powder purity, size distribution, and mixing are important aspects in the early process stages. Additives include sintering aids; binders to provide green body strength during handling and machining; and plasticizers, wetting agents, and deflocculants to provide the necessary rheological properties during shaping. Important shaping processes include isostatic pressing, extrusion, and hot pressing for relatively simple shapes, with slip casting, injection molding, and green machining used for more complex shapes. In each case, the powder characteristics and additives must be optimized to the particular shaping and subsequent densification processes. The latter involves some form of sintering; it may be reaction sintering as in reaction-bonded silicon nitride (RBSN, see Section 9.3.7) or reaction-bonded silicon carbide (RBSC) and can occur at pressures ranging from atmospheric (pressureless sintering) to >1000 atm (100 MPa) in hot isostatic pressing. Final machining of densified ceramics is difficult and should be minimized as much as possible by the production of net shapes. Full understanding of the mechanisms involved in material removal is essential in minimizing machining damage. The various process stages are discussed in detail in [96].

9.3.2. Thermal Shock Resistance

The ability to withstand rapid temperature changes is a requirement in some ceramic applications. The physical properties of ceramics determine the stress generated and, consequently, the thermal shock resistance because, unlike metals, ceramics cannot deform plastically to redistribute stress. A broad indication of relative thermal shock resistance can be obtained from the equation

$$\Delta T = \frac{\sigma_f\,(1-\nu)}{E\alpha}$$

where ΔT is the temperature change that the material can withstand without exceeding the fracture stress σ_f, E is Young's modulus, α is the coefficient of thermal expansion, and ν is Poissons ratio. Typical values of ΔT calculated according to this equation are given in Table 20. Only a limited number of ceramics are likely to be used in environments involving severe thermal cycling, such as the gas turbine engine, because of these considerations. Silicon nitride and silicon carbide are the ceramics with the earliest potential application.

Table 20. Thermal fatigue resistance of ceramic materials

Material	ΔT, °K
ZrO_2, fully stabilized	80
Al_2O_3, 99 %	100
Sintered SiC	215
Reaction-bonded Si_3N_4	250
Sintered Si_3N_4	625

9.3.3. Component Design and Life

The inability of most ceramics to redistribute stress by plastic deformation increases the importance of accurate prediction of both steady-state and transient stress in component design. This prediction requires advanced three-dimensional thermal and stress analyses including finite element techniques, which permit accurate analysis of the whole component. The traditional design techniques used for ceramic components have been probabilistic in approach. Brittle materials such as ceramics are very sensitive to flaws, and the Griffith equation provides the basis for understanding the relationship between short-term strength, critical crack size, and fracture toughness:

$$\sigma_{\mathrm{f}} = \left(\frac{2E\gamma}{\pi c}\right)^{1/2}$$

Where σ_{f} is the fracture strength, E the elastic modulus, γ the fracture surface energy, and c the flaw size which will propagate at local stress σ_{f}.

One approach to the preparation of stronger ceramics is to reduce defect size [97]. Powder processing, fabrication, and surface finishing of components were identified as key factors in this approach.

Figure 64. Typical stress – probability – time (SPT) diagram Time, s: a) 10^7; b) 10^5; c) 10^3; d) 10

Life prediction requires knowledge of the size of defects present in the material. Weibull statistics have been used in life prediction of ceramic components. The technique involves the construction of strength – probability – time (SPT) diagrams of the type illustrated in Figure 64 [98]. These are produced from test data generated under relevant test conditions including time-dependent tests.

The Weibull approach was intended to allow the prediction of stress levels with the required survival probability. Some success has been claimed in low-temperature applications [99]. Accurate specification of flaw size by statistical strength characterization is difficult, however.

At high temperature, additional effects produce microstructural or chemical changes in the material, including localized plastic flow, which can induce crack healing or generate creep voids; oxidation, which can heal cracks or introduce new defects; and microstructural changes such as grain growth, phase changes, or surface evaporation. Thus several high-temperature effects can influence strength, and the original defect population present at ambient temperature is not always an accurate reflection of how a material will respond mechanically to stress at high temperature. Another problem is that the small size of critical flaws, possibly in the range of 1 – 100 µm, limits the applicability of nondestructive testing in quality assurance.

A complementary approach to ensuring the specified component strength is proof testing. This has been applied but can introduce additional problems, because the proof test itself can modify the flaw population [100].

The basic problem with the traditional probabilistic approach, however, is that new flaws can be created during service operation and this would invalidate any performance predictions.

9.3.4. Defect Tolerance

Appreciation of the limitations of the traditional lifing approach has led to the realization that for successful application in environments with significant tensile stress, the defect tolerance of ceramics must be increased. This can be achieved in several ways. The fracture toughness of silicon nitride containing Al_2O_3 and Y_2O_3 sintering aids can be doubled by controlling the

sintering parameters to introduce high aspect-ratio grains of β-Si_3N_4 into the microstructure [101]. The expansion accompanying transformation from the tetragonal to the monoclinic form of ZrO_2 has been used to produce toughening in several ceramics. Increasing interest has been shown during the last decade in whisker- and fiber-reinforced ceramics. Sintered Al_2O_3 has a fracture toughness of ca. 2 MPa $\cdot$ $m^{1/2}$, and the incorporation of 20 vol % of SiC whiskers increases this to 8 MPa $\cdot$ $m^{1/2}$. Since 1990 there has been major activity to develop ceramic composite materials in which the incorporation of fibers introduces significant toughening [102] (see Chap. 13).

9.3.5. Alumina

Alumina is currently the most highly developed engineering ceramic. A wide range of high Al_2O_3 ceramics is produced under different trade names, with the Al_2O_3 content varying from 85 to >99 %. Strength and temperature capability increase with Al_2O_3 content, as shown in Table 21 [103], but shaping capability decreases with increasing Al_2O_3. The balance of the composition involves SiO_2, MgO, and other additives to aid shaping and to control sintering temperature. The microstructure of high-Al_2O_3 ceramic contains some glassy phase arising from the sintering additives. Poor thermal shock resistance (see Table 20) and the difficulty of machining sintered material to obtain high dimensional accuracy of complex-shaped components limit the applications of alumina. Indeed, the hardness of α-Al_2O_3 (corundum) has long been utilized in abrasives, either in the form of loose grains or bonded material in grinding wheels. The use of Al_2O_3 as a cutting tool was first considered in the late 1930s, but not until 20 years later could strong, fine – grained, high-quality alumina tool bits be made. Hardness retention at high temperature is an important characteristic because tool temperature can reach 1000 °C during the machining of ductile materials such as steel. A recent development has been to incorporate silicon carbide whiskers in Al_2O_3, which increase the thermal conductivity and, consequently, the thermal shock resistance. They also significantly increase toughness (Section 9.3.4), which has led to improved tool performance.

Table 21. Effect of composition on properties of alumina materials

Property	Al_2O_3 content		
	90 %	95 %	99 %
Modulus of rupture, MPa	200	350	550
Young's modulus *E*, GPa	200	300	400
Softening temperature, °C	1600	1750	1900

Sintered Al_2O_3 is also used for missile radomes (external containers for radar and other equipment). The radome must be transparent to radar signals which requires particular dielectric properties; as an external surface, it is also exposed to aerodynamic and thermal effects during flight.

9.3.6. Zirconia

Zirconia is a highly refractory material, *mp* 2680 °C, which is polymorphic, with a monoclinic phase stable to ca. 1170 °C, a tetragonal phase stable from 1170 to 2370 °C, and a cubic phase stable to 2680 °C. The monoclinic – tetragonal phase change is accompanied by a volume change of ca. 4 %, which is large enough to cause spontaneous failure on cooling large pieces of pure ZrO_2. Phase transformation must, therefore, be prevented in applications such as metal melting crucibles, atomizing nozzles, and extrusion dies. This can be achieved by the addition of CaO, which stabilizes the cubic form of ZrO_2 from room temperature to its melting point.

The volume expansion during the tetragonal to monoclinic phase change can be used to advantage to improve both the strength and the toughness of ceramics. This concept was first proposed in 1975 [104] for a ZrO_2 material and has since been applied to other ceramics. Zirconia particles within a critical size range are introduced into the ceramic, and the constraining pressure exerted by the surrounding matrix retains the tetragonal structure in the ZrO_2. If a crack grows in such a ceramic, the tensile stress around the advancing crack tip allows the tetragonal – monoclinic transformation to take place. The resulting expansion introduces a compressive stress around the crack tip, thereby reducing its tendency to propagate [105]. The addition of 15 vol % ZrO_2 to Al_2O_3 improves fracture toughness to 12 MPa $\cdot$ $m^{1/2}$ [106], and such material is used commercially in modern

Al_2O_3 cutting tools. Transformation toughening in ZrO_2 is achieved by isothermally aging a partially stabilized ZrO_2 (ZrO_2 – 3 % MgO) at 1400 °C to develop small tetragonal precipitates in a cubic matrix (Fig. 65) [106]. This material is used for cutting and slitting industrial materials; the insulating potential in automotive engine parts, where the low thermal conductivity is advantageous, is being evaluated. The low thermal conductivity of ZrO_2 has also resulted in its use in coating jet engine components (Section 3.4).

Figure 65. Tetragonal precipitates in transformation-toughened zirconia

9.3.7. Silicon Nitride

Silicon nitride exists in two basic forms: porous and dense. The porous form, *reaction-bonded silicon nitride (RBSN)*, is produced by controlled nitridation of a silicon powder compact in a nitrogen atmosphere at 1400 °C. *Dense silicon nitride* is made by several processes including hot pressing and pressureless sintering.

Being porous, RBSN has the lowest strength over most of the temperature range. The strength depends on bulk density, which can be controlled in the range 2.0 – 2.8 g/cm^3, compared with the theoretical density of ca. 3.2 g/cm^3. Pore morphology is an additional strength-controlling factor. Flexure strength is relatively low but is maintained to >1200 °C (Fig. 66) because the absence of sintering aids means that no glassy phases are present in the microstructure. One manufacturing advantage is that little shrinkage occurs on nitridation. Thus, the pressed and machined silicon powder shape can often be made close to the final dimensions. The porous surface can be sealed by chemical vapor deposition (CVD) of a layer of dense silicon nitride, significantly improving oxidation resistance. Reaction-bonded silicon nitride is used in light alloy foundries for pouring spouts, continuous casting dies, etc., and in heat treatment and brazing fixtures.

Figure 66. Flexural strength of silicon nitride and silicon carbide materials
a) Hot-pressed SiN; b) Sintered SiC; c) Reaction-bonded SiN; d) Reaction-bonded SiC

The production of dense silicon nitride requires the incorporation of sintering aids. Sintering may be carried out at atmospheric or slight overpressure to produce sintered material (sintered silicon nitride, SSN). Sintering takes place during hot pressing (hot pressed silicon nitride, HPSN) or hot isostatic pressing; the amount of sintering aid required generally decreases with applied pressure. Oxides such as MgO, Y_2O_3, and Al_2O_3 are incorporated as sintering aids, and densification occurs at 1600 – 1800 °C by solution and precipitation of β-Si_3N_4 from the liquid produced by the sintering aids. The resultant microstructure contains two or more phases depending on the aids used. The first widely used additive was MgO, which reacts with SiO_2 to create a low-viscosity glassy phase that limits temperature capability. A more refractory glass is produced by addition of Y_2O_3; Y_2O_3-containing materials, therefore, possess higher temperature capability (Fig. 67, see next page).

In the past decade, efforts to demonstrate the potential of ceramic components in gas turbine engines have increased. Dense silicon nitride has been used for various static and rotating turbine components and has been built into automobile turbocharger rotors.

9.3.8. Sialons

Sialons are based on a solid solution of Al_2O_3 in Si_3N_4, where nitrogen is partially replaced

Figure 67. Influence of grain boundary phase on creep properties of silicon nitride and sialon materials at 1350 °C

by oxygen and silicon is partially replaced by aluminum. They also contain additives such as Y_2O_3, because they are made by hot pressing or sintering. The second phase in such materials can be crystallized to $Y_3Al_5O_{12}$ [107]. The result is a higher temperature capability because this is not a glassy phase (see Fig. 67). Sialon containing a glassy second phase has been used for machining nickel superalloy turbine disks at a surface speed of 5 m/s, compared to a maximum of 0.25 m/s for tungsten carbide inserts [108].

9.3.9. Silicon Carbide

Silicon carbide is manufactured in three major ways: reaction bonding, sintering, and hot pressing. Reaction-bonded silicon carbide (RBSC) is produced by infiltrating molten silicon into a powder compact of SiC and carbon. Silicon reacts exothermically with carbon to form silicon carbide and bonds the structure together. Not all of the silicon reacts, however, and the final material contains free silicon, usually more than 8 vol %. A major limitation on temperature capability exists because silicon melts at ca. 1400 °C (see Fig. 66). Although RBSC has been used in developmental gas turbine engines, the major applications (e.g., pump seals) make use of its excellent wear resistance.

Higher operating temperatures are possible with sintered and hot-pressed material. Hot pressing with the addition of Al_2O_3 can give full densification, whereas sintering is achieved by addition of boron and carbon. Cubic β-SiC was used initially, but the growth of large transformed grains of the high-temperature α phase in the β matrix made processing difficult. Subsequently, α-SiC was successfully sintered. The usual manufacturing route is to press blanks, machine in the green state, and then sinter.

Silicon carbide and silicon nitride have been used for major high-temperature components in ceramic gas turbine demonstrator programs during the past decade.

9.3.10. Glass Ceramics (→Glass Ceramics)

The concept of manufacturing polycrystalline materials from glass is ca. 200 years old and has undergone major development in recent years. The use of glass-shaping technology allows automated production of relatively complex shapes with close dimensional control. The molten stage leads to excellent property consistency to which the fine grain size (typically

1 – 5 μm) contributes. Bend strengths of 75 – 400 MPa are possible, with temperature capabilities approaching 1400 °C, depending on composition.

In the manufacturing process, a glass of selected composition, incorporating nucleating agents for crystallization, is melted and shaped. It is then crystallized by a duplex heat treatment sequence with a lower temperature nucleation stage followed by a higher temperature crystallization growth stage. Early nucleants included gold, silver, copper, and platinum; more recently, P_2O_5 and TiO_2 have been used. Typically up to 95 % crystallization is obtained with some residual glass. Expansion coefficient, dielectric properties, and temperature capability depend on glass composition. Cordierite ($2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$) has been used for missile radomes, and a lithium aluminum silicate with low coefficient of expansion is used for domestic cooker hobs. Coefficients of expansion can be tailored to match many metals, and glass – metal joints can easily be made by using a controlled oxide on the metal to provide a good bond with the glass ceramic.

10. Carbon and Carbon – Carbon Composites (→Carbon)

Carbon occurs naturally as graphite and was used for alloy-melting crucibles as early as the fifteenth century [109]. Carbon and graphite have been used in various manufactured forms in high-temperature applications that require high mechanical strength and good thermal shock resistance since the beginning of the twentieth century. Low elastic modulus, low coefficient of thermal expansion, and high thermal conductivity contribute to the good thermal shock resistance. Unlike other materials, the strength of graphite increases with temperature: at 2400 °C, it is approximately twice as strong as at 0 °C. Oxidation resistance above 500 °C in air, however, is poor.

Carbon and graphite can be made in various forms from the almost perfect crystalline structure of pyrolytic graphite to the amorphous structure of glassy carbon and carbon black. Shaped carbon products are made in the following way: a mixture of crushed petroleum coke, coal, or lampblack with a binder, such as pitch or tar, is extruded or pressure-molded to shape and then baked in gas-fired furnaces with a controlled temperature rise from 700 to 1200 °C to drive off volatiles and carbonize the binder. Furnace time varies from a few days to several weeks depending on size. Graphite is made from petroleum coke in a similar way, except that after baking at 950 °C, it is graphitized at 2600 – 2800 °C in resistance furnaces for a total cycle time of 350 – 700 h. All manufactured graphites consist of microcrystalline graphite particles in an amorphous carbon matrix.

The primary use of carbon and graphite (in terms of tonnage) is in electrodes for electric arc furnaces, where the higher electrical conductivity of graphite enables the production of an electrode with half the cross-sectional area of a carbon electrode having the same current-carrying capacity [110]. The other major use in metal processing is in carbon blocks for lining furnaces, including blast furnace hearths. Because they are not wetted by molten metals, graphite molds are used in casting, and graphite jigs are used in brazing.

Graphite is also used extensively in resistance and induction-heated furnaces. The low vapor pressure of graphite allows it to be used as a heating element up to 3000 °C in inert or reducing atmospheres and up to 2500 °C in vacuum. Complex machined shapes are often employed to increase the electrical resistance of the element. Graphite is also used for susceptors in indirect induction heating furnaces. Pyrolytic graphite is a highly anisotropic form of graphite with thermal and mechanical properties that depend strongly on crystal direction. It is produced by chemical vapor deposition from methane; carbon is deposited onto a suitable substrate held at ca. 2000 °C. The carbon grows as a highly oriented graphite structure with the *c* axis of the crystallite normal to the substrate surface. The resultant material has thermal conductivity in the *a* direction ca. 100 times that in the *c* direction (Fig. 68). Thus in the direction perpendicular to the basal plane, pyrolytic graphite has one of the lowest thermal conductivities of all solid insulating materials at high temperature. For this reason, it has been used for rocket nozzle inserts and nose tips in reentry vehicles. Brittle failure problems were encountered with some of these components, and the need for a tougher material was met by carbon – carbon composites, which

were produced fortuitously in the laboratory in 1958 [111].

Figure 68. Relationship between thermal conductivity K and crystal direction in pyrolytic graphite ($K_a \approx 100\,K_c$)

Carbon – carbon composites are a logical evolution of carbon fiber-reinforced resin composite systems [112]. Carbon fibers are usually made by heat treating polymer fibers (e.g., polyacrylonitrile) at ca. 250 °C under tension in air to oxidize and stabilize the fibers (see also →Fibers, 5. Synthetic Inorganic, Chap. 5.). They are then heated to 2500 °C under tension to orient the graphite planes along the fiber axis. Fibers thus produced are ca. 10 µm in diameter and are available as tows of large numbers of individual fibers. Process parameter selection allows fiber properties to be varied (Table 22).

Table 22. Properties of various carbon materials

Carbon material	Flexure strength, MPa	Young's modulus, GPa
Fine-grained monolithic graphite	15	7
High-modulus carbon fiber	2000 ∗	400
High-strength carbon fiber	3500 ∗	200
Unidirectional carbon – carbon composite, longitudinal	1250	160
Unidirectional carbon – carbon composite, transverse	10	

∗ Strength in tension.

A typical component is fabricated from carbon fiber and a suitable resin by a technique such as molding or filament winding, then carbonized, and densified. The resin should have a high char yield, resulting in the selection of phenolic or other resins rather than epoxides or polyimides. The carbonization is carried out in an inert atmosphere at 1000 – 1100 °C to pyrolyze the resin and form a carbon residue. The resultant weak and porous carbonized component is then densified either by reimpregnating with a resin and recarbonizing or by chemical vapor deposition at 800 – 1500 °C with a hydrocarbon gas. Several resin impregnation – carbonization cycles are necessary to achieve the densification level required for the specified strength. Further heat treatment may be necessary depending on application, e.g., at 1500 °C to improve oxidation resistance to some extent or at 2500 °C (graphitization) to increase thermal stability and thermal conductivity.

The toughness of carbon – carbon composites is illustrated by the work of fracture of 60 – 125 kJ/m^2 [113], depending on final heat treatment. The elastic properties are similar to those of carbon fiber-reinforced plastic analogues, but the strength is much lower because of the low failure strain of the carbon matrix (typically 0.2. % compared with 2 % for a resin and 0.5 – 1 % for fibers) and the high porosity inherent in carbon – carbon composites. The strength increases with temperature to ca. 2000 °C, and significant strength is retained as high as 2800 °C. The composite material is no more resistant to oxidation than monolithic graphite. This is not a major problem in single-mission applications (e.g., rocket nozzles or cruise missile engines) or when the material experiences only brief expossure to high temperature and design allows a measure of oxygen exclusion (e.g., aircraft brakes).

The major reason for using carbon – carbon brakes is the saving in weight relative to conventional metal brakes. The high specific heat of carbon allows heat developed from the kinetic energy to be absorbed, and the excellent high-temperature strength is needed to cope with the 1200 – 1500 °C temperature developed by extreme braking during an aborted takeoff in advanced military aircraft. Carbon also possesses the friction and wear characteristics required for brake applications.

For more long-term, high-temperature applications, some form of oxidation protection is required [114]. The external surface of the space shuttle orbiter vehicle reaches a temperature of ca. 1500 °C in the nose cone and wing leading edges during reentry [115]; carbon – carbon composite protected with an external coating of silicon carbide is used. The coating is applied by encapsulating the part in silicon carbide, silicon, and alumina powder and heating to ca. 1650 °C. The silicon vapor that forms reacts with carbon to form the SiC coating. The SiC cracks during the coating cycle, because of the large difference

in expansion coefficient between the SiC coating and the substrate, and the final step is to seal the cracks by impregnation with a silicon compound such as tetraethoxysilane [111].

For potential jet engine applications involving a greater degree of thermal cycling and extended dwell times at ca. 1000 °C (in addition to high-temperature excursions >1500 °C), improved oxidation resistance is required, and techniques such as matrix inhibition are being developed. Glass-forming elements are incorporated in the matrix material so that glass forms as cracks are generated, thereby protecting the base material from further oxidation.

11. Ceramic Composite Materials

The initial developmental motivation for ceramic matrix composite materials was similar to that for carbon – carbon composites: the need to increase the toughness of the unreinforced material. Work on carbon – carbon composites in the early 1960s demonstrated that significant toughening can be achieved in brittle matrix materials by incorporating suitable fibers. The strength of the interface between fiber and matrix must be controlled to ensure that sufficient energy is absorbed by debonding at the fiber – matrix interface, by post-debonding friction as the fibers are progressively pulled out, and by unbroken fibers that were circumvented by the crack in the matrix (Fig. 69). Too strong an interface will not deflect cracks and will result in brittle failure.

Figure 69. Schematic illustration of energy-absorbing phenomena in a brittle-matrix composite material

In the late 1960s carbon fibers were incorporated in Pyrex glass matrices, and high-strength, tough composites were produced (Fig. 70) [116].

Figure 70. Stress – strain behaviour of unreinforced and reinforced glass

Subsequently carbon fiber reinforced glass ceramics were produced, but the temperature capability was limited by the oxidative instability of the carbon fibers. In the early 1980s, the availability of the organometallic-derived Nicalon SiC fiber changed the situation. The properties of carbon and Nicalon fibers are compared in Table 23. Nicalon fiber has far superior oxidation resistance to carbon fibers, and during the 1980s major programmes were carried out to develop a SiC-reinforced glass ceramic composite capable of operation at 1000 °C and above [117]. The simplest manufacturing route involved impregnating monolayer tapes with a slurry containing glass ceramic powder, a resin binder, and water; stacking the tapes, burning out the resin binder; and densifying the compact by hot pressing. The importance of controlling the fiber – matrix interface was confirmed. A carbon-rich layer some 25 µm thick was formed at the interface during processing. This layer forms a bond of sufficient strength to allow load transfer but allows fiber debonding and pull-out during crack propagation and thus develops good toughness [118]. Combustor components made of Nicalon – glass ceramic composite were run in a military engine programme in 1993.

Table 23. Properties of reinforcing fiber materials

Fiber	Strength, GPa	*E*, GPa	Diameter, µm
Carbon, high-modulus	2.5	490	8
Carbon, high-strength	5	290	8
Nicalon	2.8	190	15

Glass ceramic matrix composites did not have the temperature capability necessary for projected engine designs, however, and materials with higher temperature capability were

necessary. This led to the development of Nicalon – silicon carbide ceramic matrix composites [119]. In the manufacture of these composites, a low-density Nicalon preform is produced. The preform can be created by a variety of processes including filament winding, weaving, and braiding [120]. The fibers are pre-coated with a thin layer of carbon to develop the appropriate interface properties. Chemical vapor infiltration (CVI) of the preform with a gaseous precursor such as a chlorosilane forms the matrix of the composite [121]. The rate of deposition is low, and several infiltration cycles are likely to be required, depending on component sizes, to produce the required composite density. Liquid infiltration with a polymeric precursor followed by pyrolyzation is an alternative to CVI, but again, multiple re-infiltration may be required. Nicalon – SiC composites have good toughness but the temperature capability of the composite is lower than that of monolithic silicon carbide (Fig. 71). A major factor in this is the nonstoichiometry of the Nicalon fibers, which contain oxygen and excess carbon.

Figure 71. Temperature dependence of strength for silicon carbide materials
a) Sintered silicon carbide; b) Nicalon – silicon carbide composite

Toughness is reduced after high temperature exposure because of the oxidative instability of the carbon layer which controls interface properties. Nevertheless, exhaust nozzle flaps were flight engine tested on military aircraft in 1989 and have been standardized in some applications.

Despite the progress made in the development of ceramic matrix composite technologies, further work is needed in several areas in order to achieve the full potential of these technologies [122, 123]. These have been defined as:

- Fibers with higher temperature capability
- Cheaper manufacturing technology
- Optimization of fiber – matrix interface behavior
- Development of relevant design methodology and life-prediction capability

Considerable work is in progress to develop improved fibers, including oxide-based fibers, single-crystal oxide fibers, and mixed-oxide fibers. The cost of manufacturing processes is being addressed [124]. The Lanxide process involves reaction between a vapor phase and a molten metal alloy, with the reaction product growing through a fiber preform. Large complex shapes have been manufactured in a variety of ceramic systems, including automotive and jet engine components. Work is also in progress to develop stable interfacial coatings for composite systems of various types, including oxide – oxide composites.

12. Intermetallic Materials

Intermetallic materials (see also Intermetallics) consist of phases formed by two or more metals combining in integral ratios. Their crystal structure is usually ordered with each constituent metal occupying a particular sub-lattice. The ordering tends to increase high-temperature strength by inhibiting diffusion and creep deformation. Intermetallic materials have significant potential for high-temperature operation but are usually brittle at ambient temperature because slip systems are limited. Major development activities have hence aimed at improving toughness while retaining or increasing high-temperature capability. The lower density intermetallics such as titanium aluminides are of particular relevance in aerospace applications where minimum weight is essential. Nickel aluminides have considerable potential at temperatures beyond the capability of titanium aluminides, and iron aluminides have been developed as low-cost materials with good corrosion resistance. The various manufacturing techniques appropriate for intermetallic materials are discussed in [130].

Titanium Aluminides. Materials in the Ti – Al system have been the subject of major research since the early 1960s, particularly Ti_3Al and TiAl materials. Development of Ti_3Al has led to the Super-α_2 material which contains

15 % Al, 2 % Nb, 3 % V, and 2 % Mo. Its strength is comparable with that of conventional titanium alloys. It has higher temperature capability, currently limited to 600 – 700 °C by embrittlement due to oxygen penetration [131]. Demonstration parts have been run in jet engines with weight savings of around 40 % compared with nickel superalloy components.

TiAl materials have higher temperature capability than Ti_3Al although protective coatings may be required at temperatures above about 800 °C. A duplex-structure material containing some Ti_3Al phase with additions of chromium and niobium has a useful level of toughness, and components have been produced by casting and by powder manufacturing techniques. Automotive turbocharger rotors and exhaust valves have been trialled, and low-pressure turbine blades have been run in a jet engine and demonstrated significant weight saving relative to conventional nickel superalloy blades [132].

Nickel Aluminides. Ni_3Al was the first material studied in the Ni – Al system, largely because it is the strengthening phase in nickel superalloys and it has inherent oxidation resistance. Chromium additions have increased the high-temperature oxidation resistance, and ambient-temperature toughness and ductility have been improved by the addition of small quantities of boron. Optimum properties are developed in alloys containing some nickel solid-solution phase [133], and materials of this type have been used in diesel engine components.

NiAl materials have lower density and higher oxidation resistance than Ni_3Al and are thus of more potential interest in aerospace applications. High-temperature strength is improved to a useful level by the presence of an Ni_2AlTi second phase, but methods to improve the ambient-temperature brittleness have not yet been developed, and further work is required.

Iron Aluminides. The principal advantages of iron aluminides are oxidation and corrosion resistance that are superior to those of commercial ferritic heat-resistant iron-base alloys together with reduced materials costs. Early aluminides were brittle and had low strength at high temperature. Improved understanding of material behaviour and of the effects of alloying led to the development of strong, ductile Fe_3Al and FeAl materials [134]. Early applications could be in coal-combustion technologies because of the excellent oxidation and corrosion resistance of these materials.

Other Intermetallics. The intermetallic materials discussed above have mostly found some commercial application or have been subject to demonstration programmes which have indicated directions for further work. There are other intermetallics which are more speculative but may have the potential for even higher temperature capability. Molybdenum disilicide has seen commercial usage in heating element applications. An SiO_2 scale provides protection at high temperatures but oxidation is very rapid at lower temperatures around 450 °C. This type of behavior occurs in a range of intermetallic materials and is not fully understood [135]. Further work is in progress to address the ambient-temperature brittleness of $MoSi_2$ and to increase high-temperature strength. Reviews on a wide range of intermetallic compounds with the highest melting points have been carried out [136] in order to provide guidelines for future R & D programmes.

13. Thermal Ablative Materials

Some environments generate temperatures capable of vaporizing most known engineering materials, e.g., hypersonic reentry vehicles can approach 8000 °C. Materials with specific characteristics are required to withstand such temperatures by using *thermal ablation*.

The use of materials as a heat sink is a long established technique that employs the heat content of the material in the solid state. This is typically ca. 10 % of the total heat-absorbing capacity of a material, including melting and vaporization. The total heat capacity is employed in thermal ablation, which is defined as the consumption of solid material by using the total heat capacity and an air flow to continuously remove the products formed. Materials for ablative application should possess a high melting point, high specific heat, high latent heats of fusion and vaporization, and low thermal conductivity. The latter is probably the most important requirement because of the need to confine the high temperature to a thin surface region and minimize

the temperature of the structure being protected. Full ablative potential is achieved only if the material is retained at the surface long enough for it to vaporize; uniform surface removal is essential. These requirements led to the concept of a composite material with the ablative component held in place by fibers that are more refractory. Reinforced plastics are excellent ablative materials and have been used in many aerospace applications, including the Apollo reentry heat shield and Titan 3 C rocket nozzles [125].

Ablation takes place in the following sequence: the surface temperature increases rapidly because of the low thermal conductivity until thermal degradation starts; the gas produced by the volatile components in the plastic forms a boundary layer on the component and provides some insulation; the remaining carbon char is oxidized, sublimed, or eroded. The process is illustrated schematically in Figure 72.

Figure 72. Schematic representation of the ablation process

Phenolic resins have been used most commonly because of the high proportion of char formed. The char yield of a phenolic resin in a nitrogen atmosphere at 900 °C is ca. 47 %, compared with <5 % for an epoxy resin [126]. Glass fibers are often used as reinforcement; constituents other than SiO_2 are removed during ablation so the resultant surface film of viscous SiO_2 can play a useful role if the force of the gas stream is relatively low. A reinforcement level of 40 % is typical; the optimum level depends on the operating environment. Variable ablation rates of reinforced phenolic systems in some rocket nozzle applications have been reported [127]. The more thermally stable carbon – carbon composites may offer improvement because their ablation behavior is superior to that of polycrystalline graphite.

14. Thermal Insulating Materials

Insulating materials of low thermal conductivity restrict the flow of heat from one region to another. They are of two basic types, solid and fibrous.

Solid Insulators. Solid insulators are produced in the form of bricks, blocks etc. They are nonhomogeneous and contain voids, either incidentally or intentionally, that reduce conductivity. Heat transmission in fully dense materials occurs by conduction and is thereby dependent on thermal conductivity; convection through the gas contained in the pores of porous materials is an additional factor. Most solid insulators have approximately isotropic properties, but the thermal conductivity of pyrolytic graphite is very dependent on crystal direction (see Chap. 10).

Figure 73. Thermal conductivity of fibrous insulating materials and bulk insulating materials

Fibrous Insulators. Fibrous insulators are made from natural or synthetic fibers with or without chemical binding agents. They are available as batting, cloth, paper, and in a loose form for use as filler. Heat transmission occurs by conduction along the fibers and across regions of fiber contact, convection in the voids, and radiation between fibers. Conductivity is influenced

strongly by bulk density and fiber diameter; the net result is minimum thermal conductivity at a characteristic packed density [128]. Although actual conductivity depends on the factors mentioned, fibrous insulators, as a family, have significantly lower conductivity than solid insulators (Fig. 73, see above). Strength generally increases with bulk density and any chemical fiber bonding that may be used (Fig. 74) [129]. The actual fiber material makes a relatively minor contribution to the overall thermal conductivity but determines the temperature capability of the insulator (Table 24).

Figure 74. Effect of bulk density on strength of fibrous insulating materials
a) $SiO_2 - Al_2O_3$ fibers bonded with BN; b) SiO_2 – aluminum borosilicate fiber system; c) Rigidized fibrous SiO_2

Table 24. Temperature capability of fibrous insulating materials

Fiber material	Maximum use temperature, °C
SiO_2	1250
$Al_2O_3 \cdot SiO_2$	1350
Al_2O_3	1750
ZrO_2	2200
Carbon	2700

Fibrous insulating materials are used as hot-face linings in heat treatment furnaces, where their lower weight and thermal mass result in faster heating and cooling rates and, consequently, reduced cycle time and fuel savings over conventional refractories. Other applications include combustion chamber and pipeline insulation in the petrochemical industry, and burner components and imitation coals in domestic coal-effect gas fires. Rigidized silica fiber tiles are used on the space shuttle orbiter *Columbia* in which the silica fiber structure supports a glass-coated outer skin that radiates a high proportion of the heat energy back to the atmosphere.

1. Introduction [1–6]

Holography is the field of optical science in which *wavefronts* are recorded, stored, and recovered. Holograms are often used for virtually perfect three-dimensional lensless photographs and they also have a number of important technical applications such as diffractive optical elements, holographic filters for optical processing, and optical memories.

Holography can be described, in general, as the technique of using diffraction to transform one wavefront into a second in a prescribed manner. These transformations include, for example, sunlight into a three-dimensional scene (an example of pictorial holography), or an expanding wave into a converging wave and image (an example of a holographic optical element). A *hologram* is generally a two-dimensional mask which contains structures with details on the order of the wavelength of the wavefront being transformed. The technique of holography may be applied in the entire spectrum of *electromagnetic waves* including visible, infrared, ultraviolet, and X-ray regions. *Nonelectromagnetic waves* may also be transformed by holography, e.g., acoustic waves and matter waves (such as electrons). The hologram effects desired wavefront transformations by imposing spatially varying amplitude and/or phase modulations on the incident wavefront. The modulated incident wavefront is thereby diffracted into the desired wavefront as it propagates through and from the hologram region.

2. Operating Principles of Holography

The recording and viewing of a *two-beam transmission* hologram is perhaps the most direct way to give an understanding of holography. In Figure 1 (see top of next page) the reflected wavefront (W) from the pyramidal object (P) is recorded at the hologram plane (H) using a reference beam (R) from the same laser (L). The recording film medium (H) is developed and returned to its original position. Viewing of the reconstructed wavefront (W) is accomplished by illuminating the developed medium (H) using the same illumination beam (R) as used in the recording; however now, the object (P) is removed. The observer (E) looking toward (H) as in Figure 2 sees a perfect three-dimensional reconstruction of the pyramid (P) by virtue of the reconstructed wavefront.

Several important types of holograms have been devised, including Gabor's single beam, Leith and Upatnlek's two-beam, Denisyuk's reflection type, image plane, Fourier, and Fraunhofer holograms [1–3]. The "holographer's rule"

Figure 1. Layout for recording a hologram

is a valuable aid to gain insight into the reconstruction of any of these types. Consider a large number of plane waves represented by rays (1 – 4), incident on the holographic medium (H) in Figure 3. After processing, the plate is returned to its original position and any one of the *original beams* can be used for the reconstruction. The rule is that if any beam, e.g., ray (3), is used as the reference beam (3-R in Fig. 4), all other beams present in the "taking" will be reconstructed as shown, together with some spurious rays (see Section 2.2) which can often be minimized in practice. These reconstructed primary beams will be traveling in the same direction as they were in the original scene.

Figure 2. Hologram (H) is illuminated by a reference wave (R) for viewing by observer (E) who sees a perfect three-dimensional reconstruction of the pyramid in its original position (virtual)

A hologram can also be illuminated with a *reversed reference beam* (3-R$^-$) as shown in Figure 5 (see next page). In general this gives rise to what is termed the *conjugate wavefront* W$*$ which is the recorded wavefront but traveling back on itself. The holographer's rule for this reconstruction is shown in Figure 5.

If the same hologram as was made in Figure 1 is illuminated with a reversed reference beam, ray (R$^-$) (see Fig. 6) the conjugate wave W$*$ is set up propagating in space back toward the former position of the pyramidal object. An observer (E_2), looking into H, sees points of the pyramid in their true positions relative to the original, however the visual perspective is reversed. This reversal causes a false stereo perspective which is termed pseudoscopic; and the observer located at E_2 in Figure 6 perceives a

Figure 3. Recording of separate beams (1) through (4)

Figure 5. Viewing of the conjugate reconstruction of the hologram from Figure 3 with the reference illumination provided by using a reversed beam 3 (3-R^-)

Figure 6. Viewing of the pseudoscopic image from the hologram (H) of Figure 1 using a reversed illumination R^-

Figure 7. Viewing of a reflection type hologram (H_R) in which the illumination (R^-) and the reflected reconstructed wavefront (W) are on the same side of the hologram as the observer (E)

left-to-right reversal, e.g., of points (2) and (3), as well as a depth inversion, i.e., (4) is closer to the observer than (2). If the subject had been a person's face, this pseudoscopic real image has the perspective of a "death mask."

A *reflection-type hologram* is made by bringing the recording reference beam in from the opposite side of the plate, e.g., along ray (R^-) in Figure 7. Reconstruction is as shown in Figure 7 with the observer viewing the wavefront W reflected from the hologram (H_R). For this type of hologram, the basic interference structure is a multilayer, and it is highly efficient in reflecting W only over a relatively narrow band of wavelengths. Hence, in practice, the reflection-type hologram can be viewed with incident white-light illumination, because only a narrow band is reflected and the other wavelengths are transmitted. Viewing is often improved somewhat if the hologram H_R is backed with a black, light absorbing paper or paint.

The diffracting structure for a hologram can be formed interferometrically, as described above, or it can be calculated and written fringe-by-fringe using modern digital techniques. These computer-generated holograms are made typically in two or more step: (1) theoretical analysis of the diffracting structure corresponding to a given object, (2) printout of the initial hologram pattern to a scale set by the plotter, and (3) photoreduction to a convenient scale for illumination by a visible optical beam. Theory and performance for this important type of hologram are given [2–4, 6–8].

2.1. Recording Technique

Consideration of a few practical matters and of tradeoffs often encountered in holography is useful in understanding holograms and their characteristics. Perhaps the most common method of making a hologram is to record the interference of two or more coherent waves in a photographic film of high resolution. This is illustrated schematically in Figure 1, where the coherence between the reference and object waves is obtained by splitting them from the same laser beam. For light from a laser (→Lasers), the coherence requirement which insures good contrast in the interference fringes is that the maximum difference in path lengths between the reference and the object beams after they are split should be a small fraction of the coherence length of the light. The coherence length is given by $c/\Delta\nu$ where c is the speed of light and $\Delta\nu$ is the spectral bandwidth of the light. The coherence length ranges from the order of a

centimeter for a multi-longitudinal mode argon-ion laser to about half a meter for a helium-neon laser and to thousands of meters for a gas laser running in a single longitudinal mode, which is commonly induced by an intracavity etalon in the laser.

Exposure times vary widely with the type of laser used and the recording material, but are often in the range from a fraction of a second to several minutes. Care must be taken to assure that the fringe pattern is stationary for the duration of the exposure. Because a fluctuation as small as half a wavelength in one of the beam paths, e.g., as caused by a vibrating mirror, can wash out the recorded fringe pattern, sources such as building vibrations, acoustic noise, and thermal variations must be controlled. It is important in making holograms to have a very stable table, commonly pneumatically isolated tables are used. Another very useful technique to minimize deleterious effects of such motions is to use a fringe-locking system which may include, for example, an interferometer and electronics which drive a galvonometer or piezo-electric mirror mount to counter fringe shifts detected by the interferometer.

In many technical applications of holography, the required diffracting structure can be computed; or it is otherwise known digitally, and relief forms of holograms are appropriate. Photolithographic methods employing photoresists (→Imaging Technology, Chap. 3.4.1.) are used with combinations of direct exposure, electron-beam writing, or ion-beam milling. The techniques used are similar to the manufacture of binary optics or of compact video and audio discs (→Information Storage Materials). A relief image is prepared on a master photolithographically; and thereafter, embossed holograms can be mass produced using pressure-sensitive molding.

2.2. Diffraction Efficiency [1–6, 9, 10]

The efficiency with which a given type of hologram diffracts an incident wavefront into a desired one depends on many parameters and tradeoffs. Holograms that cause diffraction by a spatially varying *absorption* are generally less efficient than those utilizing *lossless phase variations* to diffract the incident field. Whether a hologram is lossy or lossless depends on the choice of the recording medium and the processing (see Chap. 3). In addition to possible absorption in the holographic medium, much energy may be lost to spurious diffracted orders and diffuse scattering in the recording material. Spurious diffraction refers to wavefronts generated by the hologram above and beyond the idealized original recording wavefronts described in Chapter 2. Further, holograms may be grouped into *thin* and *thick* categories depending roughly on whether the modulation spatial period is much less than or much greater than the actual thickness of the diffracting structure. Thin sinusoidally modulated holograms tend to exhibit diffraction efficiencies below 6.25 % and 33.9 % for absorption and lossless media, respectively [2]. Shaping or "blazing" the diffracting structure can greatly increase the diffraction efficiency of thin lossless holograms, to levels approaching unity.

The diffraction efficiency of lossless holograms can also be enhanced to nearly 100 % by utilizing *volume diffraction*, i.e., the thick hologram regime. In volume holograms, the energy diffracted into spurious orders may be dephased with the result that essentially all the incident energy may be diffracted into a desired order. This ideal limiting efficiency may be somewhat reduced for the case of a complicated wavefront as originating, for example, from a diffuse extended object. Finally, there are many tradeoffs that arise in attempting to optimize the efficiency of a hologram. For the volume hologram example, 100 % peak diffraction efficiency may be approached for a given combination of spatial period, modulation strength, fringe tilt angle, emulsion thickness, incident angle and wavelength. However, as any of these parameters are varied from this optimum the efficiency usually decreases. Generally, the thicker the element is, the more rapidly the efficiency drops with any such parameter detunings. In many applications (e.g., a holographic lens), it would be desirable to maintain high efficiency over large wavelength shifts and/or incident angle shifts. Decreasing the element thickness results in broader spectral and angular bandwidths, but also in lower peak efficiencies. Compromises of this type can result in elements that exhibit peak efficiencies >98 % and spectral bandwidths on the order of 400 nm centered in the visible.

3. Materials Used in Holography
[1–6, 11]

Recording materials often limit the quality and performance of holograms, and are therefore of central importance. Several basic requirements of a photosensitive material for the interferometric recording of holograms include (1) a mechanism for mapping the interference pattern during exposure into an amplitude and/or phase variation in the reconstructing waves; (2) spectral sensitivity to the wavelength(s) used in recording; and (3) spatial resolution capable of following variations in the interference pattern, which are typically on the order of the wavelength used. As the angle between the reference and object beam increases, the spatial period of the fringe structure decreases (see Section 4.2.1). For 30°, 60°, and 180° beam separations, the fringe spacings setting the resolutions are 2 λ, λ, and $\lambda/2$, respectively. Hence, a resolution of >1000 lines per millimeter is often required for optical holography. Phase modulations are imparted to the reconstructing wavefront by varying the refractive index of the material, the thickness or height of the material, or more commonly, both simultaneously. It is also desirable to minimize diffuse scatter in the material both during exposure and reconstruction. Brief descriptions of a number of holographic recording materials are given below.

3.1. Photographic Materials
[12–16](→Photography)

Photographic emulsions have been useful as a recording medium since the beginning of holography. When used as an *amplitude-modulating material*, the silver-halide emulsion may be developed conventionally giving a lossy silver structure with optical density which is a mapping of the original exposure. Thick lossy holograms are limited theoretically in diffraction efficiency to 3.7 % [2], however, this is adequate for many applications. If more efficiency is useful, bleached holograms are appropriate. One means for obtaining bleached holograms is simply to use a reversal bleaching method in which the scattering centers are silver bromide instead of lossy silver [6, 16]. Earlier in bleaching methods it was common to convert the lossy silver into silver bromide. Efficiencies for the bleached hologram can reach 100 % theoretically. In practice, effects such as tanning of the gelatin during processing tend to cause surface height modulations which add a phase modulation component to both the lossy and refractive index mechanisms. Bleached holograms can exhibit higher diffraction efficiencies than their lossy counterparts, but noise (diffuse scatter) is also generally increased. To achieve the high resolutions required, the silver-halide microcrystals suspended in the gelatin of holographic emulsions must be made much smaller than in common consumer pictorial films. This results in a photographic speed of holographic films which is typically hundreds of times slower than in the latter case. Still, the speed of photographic emulsions used in holography is many times faster than in many other holographic recording materials.

3.2. Dichromated Gelatin [17–22]

The observation that the dichromate ion renders hardness and solubility of gelatin light sensitive was known in the 1800s, when dichromated gelatin was used as a resist. Dichromated gelatin is a good volume holographic recording material and many processing schedules are available [20, 21]. Whereas the theory for diffraction by phase modulating structures is well understood, the exact mechanism of volume refractive index modulation in dichromated gelatin is not fully understood. The recording mechanism is apparently dependent on the production of trivalent chromium ions from optical excitation, and the subsequent tanning (cross-linking) effect of these ions. Volume holograms recorded in dichromated gelatin exhibit diffraction efficiencies approaching the theoretical limit (which can attain 100 % in idealized cases) with low scatter noise. With dichromated gelatin, the relative humidity must be controlled during exposure and processing. The finished hologram should also be sealed to prevent deterioration. Dichromated gelatin is particularly sensitive in the blue and ultraviolet spectral regions, with essentially no sensitivity in the red. The spatial resolution of dichromated gelatin exceeds 4000 lines per millimeter. A hybrid technique is sometimes used

to increase the speed and extend the spectral sensitivity, wherein a photographic emulsion is exposed but processed so as to produce a pure gelatin medium [22].

3.3. Photopolymers [23–29] (→Imaging Technology)

Photosensitive mechanisms have been used to initiate the polymerization of a monomer, or to further link (or destroy links in) existing polymer chains. Many such processes form the basis of very useful volume phase holographic recording materials. In a broad sense dichromated gelatin (see Section 3.2) and photoresists (see Section 3.4) fall into the photopolymer category because polymeric bonds are formed or broken with exposure, giving rise to changes in solubility and/or refractive index.

An example of a photopolymer system for holographic recording is metal acrylate monomer which undergoes free radical polymerization initiated by 4-toluene sulfinic acid, which is sensitized to red light by methylene blue [25]. Advances by groups including Polaroid and DuPont have given rise to photopolymeric recording materials for holography that are capable of achieving near theoretical limits of diffraction efficiency, as well as low scatter and insensitivity to moisture. Photopolymers have been made sensitive throughout the visible range and some have exhibited spatial resolutions well in excess of $5000\,\mathrm{mm}^{-1}$. In the Polaroid material DMP-128, the effective modulation in the refractive index can be as high as 0.2 and the scattering level in the visible range is very small because the grain size in the recording is $<0.1\,\mu\mathrm{m}$. Further, these materials are roughly an order of magnitude more sensitive than dichromated gelatin.

3.4. Photoresist [29–31] (→Imaging Technology, Chap. 4.1.)

Photoresists are materials, typically organic polymers, which exhibit a marked variation in solubility with actinic exposure. Examples include PMMA, poly(methyl methacrylate), for electron exposure and Shipley AZ-1300 series resists for short-wave visible and near ultraviolet exposure. When exposure causes a decrease in solubility, e.g., by formation of additional polymeric bonds or cross-links, the photoresist is termed negative. Resists whose solubility in an appropriate solvent or developer is increased after exposure are termed positive.

In normal application, these materials are exposed and then the soluble regions removed to leave a surface-height variation which is related to the exposure. This surface relief may be used directly as a phase modulator, or it can be overcoated or etched (using chemicals, reactive ions, etc.) into the substrate. Photoresists readily reproduce sharp submicron details, and the technology of this material has been extensively developed by the electronic photolithography industry. Photoresists are important materials in holography because of their ability to map holographic exposures into surface relief. This is valuable for creating embossing masters (see Section 3.5) as well as in fabricating blazed reflection and transmission gratings and computer-generated holograms.

3.5. Embossed Films [32–35]

Mass replication of holograms is commonly accomplished through the embossing of clear or reflective films. In a typical embossing process, a master hologram is recorded in photoresist which, upon development, exhibits a surface relief mapped from the intensity distribution of the holographic interference pattern. The photoresist master is then copied onto a metal stamping master. This can be accomplished by coating the photoresist with a conductive film and then electroforming additional metal (e.g., nickel). This stamping master is then heated and pressed in contact with a thermoplastic material (e.g., polyvinyl or polyester) which is then separated from the stamping master and contains a replication of the original hologram structure. Injection molding is a common alternative. Thousands of impressions may be made from a given stamping master, and the resultant embossed plastic holograms may be reconstructed in transmission or reflection. In the latter case, the plastic is usually aluminized to enhance diffraction efficiency. Advances include embossed copies of computer-generated holographic elements with

shaped fringe structure resulting in high diffraction efficiencies.

3.6. Other Materials

In a general sense, any photosensitive medium or process capable of providing a spatially modulated refractive index or absorption may be considered for use as a holographic recording material. A few of the important materials not mentioned above are briefly discussed here.

Thermoplastic recording materials [36,37] utilize the reversible heat-softening cycle to impart thickness variations in the plastic film. For example, a photoconductor may be used to convert the optical holographic exposure into a spatially modulated electric field. Electrostatic forces from this field are then used to modulate the thickness of the softened film which, upon cooling, provides a stable lossless hologram. Spatial resolutions exceeding 1000 mm^{-1} have been obtained.

Photorefractive materials [38–40] such as bismuth silicon oxide, barium titanate, and PLZT ($Pb(Zr,Ti)O_3$) ceramics have been extensively studied as holographic materials, and also in the closely related field of four-wave mixing. One of the many possible mechanisms of refractive index modulation in these materials is the photo-induced release of electrons which drift (or are driven with an applied electric field) to a neighboring trap, where the resultant space-charge induces a local change in refractive index.

4. Uses in Chemical and Related Industries

Holography is a useful tool in a broad range of disciplines including optical elements, metrology, physics, art, medicine, and chemistry, with many of these applications given in general references [1–6,41,42]. Several applications related to the field of chemistry are described below, followed by a coarse sampling of other application areas of holography.

4.1. Holography in Chemistry

4.1.1. Study of Chemical Reactions

Holography has been used extensively to study reaction rates and diffusion parameters in chemical reactions [43–47]. In many such techniques, a volume holographic grating is formed in a test medium utilizing photosensitive chemical reactions, photochromic tracers, or other light-sensitive mechanisms. The holographic illumination usually consists of a sinusoidal intensity pattern, with a variable spatial period typically on the order of a micron, created by the superposition of two plane waves. As the photosensitive reaction proceeds, the refractive index, thickness, and/or absorption of the test medium is modulated and a probe beam is used to measure the diffraction efficiency of the induced grating, thus providing a measure of the rate of reaction. Many variations on this general technique exist including " holographic relaxation spectroscopy," where a volume grating is induced in mobile species (which are either photosensitive or tagged with a photosensitive tracer) in the test medium. When the driving interference pattern is removed, the induced grating decays as the mobile species diffuse; and the decay of the diffraction efficiency, as measured with a probe beam, is used to determine the diffusion rates of the given species.

4.1.2. Holographic Microscopy

Holography was invented by Gabor in the context of improving electron microscopy [48], and has since proven useful in a range of microscopic applications of interest to chemists [49–52]. By recording wavefronts in a microscope holographically, volumes spanning many depths of focus may be investigated without changing conditions, or alternatively, wavefronts may be superposed revealing interferometrically the effects of changes in the observed scene. In-line holograms of chemical fibers have been formed by recording the interference pattern of X-rays with wavelengths of 830 pm and reconstructing the hologram with visible light. As sources of X-rays achieve greater coherence, the ability to examine molecular structures holographically will be greatly enhanced. In the visible spectral region, the usefulness of holographic

interference microscopy for chemical investigations was demonstrated with interferometric investigations of a variety of organic and inorganic crystals [52].

4.1.3. Interferometry and Non-Destructive Testing [42,53–56].

The ability to store and reconstruct a perfect three-dimensional image makes holography very useful in interferometry and testing. For example, a hologram of a test object may be used to reconstruct an image which is exactly coincident with the object itself. Then, under laser illumination, any deformations in the object that are induced by change in temperature, pressure, stress, etc., result in interference fringes which can reveal the magnitude and direction of the displacement. This technique is sensitive to displacements on the order of the wavelength used, and may also be implemented with greatly reduced sensitivity to displacement if desired. Typical applications include the study of curing adhesives, measuring Poisson's ratio for materials, and examination of chemical bonding between concrete and smooth steel reinforcements.

4.1.4. Other Uses in Chemistry [57,58]

Holographic techniques may be applied in a broad variety of chemical studies. The combustion in engines and flames may be investigated using holography to record transient phenomena or as an interferometric tool. The versatility of holography as an analytic tool for molecular systems is demonstrated by techniques where holographic gratings are rapidly formed using interfering plane waves of 10^{-12} s duration. These transient gratings excite phonons because of electrostriction or absorptive heating, permitting the measurement of optoelastic constants, absorption, and acoustic attenuation. This type of " coherent optoacoustic spectroscopy" is used to measure the absorption spectrum of the fifth overtone transition of a C-H stretch in benzene [58].

4.2. Some Other Uses of Holography

4.2.1. Holographic Optical Elements

Holograms can perform the functions of basic optical elements, e.g., holographic diffraction gratings, holographic multilayer mirrors, diffractive lenses, chirped holograms as scanners, etc. [3,6,59]. Each type of holographic optical element has unique characteristics which often distinguish it from the more conventional counterpart. For an example of holographic optical elements, holographic diffraction gratings are discussed below.

Holography has had a strong impact on the production of diffraction gratings. First, the conventional "ruling engine" approach to scribing diffraction gratings is often replaced by a holographic exposure of photoresist and subsequent etching of the grating profile into the substrate (or direct metallic overcoating of the photoresist). The holographic exposure may consist of the interference pattern produced between two plane waves, where the period Λ along the surface of the grating is controlled by the exposing wavelength λ and the angles, θ_1 and θ_2, which the plane waves subtend with respect to the surface normal. These parameters are governed by the relation:

$$L = \frac{\lambda}{\sin(\theta_1) - \sin(\theta_2)}.$$

Diffraction gratings produced in this manner are free from "ghosts" caused by systematic ruling errors, and they can be fabricated rapidly with a large aperture. Further, holographic diffraction gratings can be recorded throughout a volume recording material rather than as a surface modulation. Such volume holograms can be recorded as transmission or multilayer reflection gratings. In the former case, they can exhibit peak diffraction efficiencies near unity and spectral bandwidths of 400 nm [60]. Holographic multilayers can be used as notch filters with bandwidths on the order of 10 nm and efficiencies of 99.99 %.

4.2.2. Information Processing

Special holographic filters are used in the field of optical information processing. The basic reason for their usefulness is that holograms can be made in the form of transmission masks that

have controllable phase delay and absorption. One of the more commonly used such masks is the holographic matched filter [2,3,6,61].

Another important technical application of holography is the field of information storage. Motion picture films, books, journals, and census data have all been successfully converted to a holographic format that provides a highly compact storage medium of archival quality [2,61].

1. Introduction

1.1. Basic Principles

1.1.1. Definitions and Classification

Definitions. Hormones are discrete substances which regulate biological function, either directly by acting on target organs or indirectly by controlling the secretion and synthesis of secondary or tertiary hormone systems [1,8,21]. They appear early in evolution. Hormonal substances have been identified in bacteria and plants which later in phylogenesis acquired functional roles in animal species. Plant hormones are treated elsewhere (→Plant Growth Regulators). The highly selective action of hormones is due to their specific interaction with cell receptors. Adaptation of hormones and

receptors is a long evolutionary process, during which the hormone receptors may change and the chemical nature of the hormone remains the same. For example, insulin controls gonadal function in certain invertebrates but in mammals it is a glucose-regulating hormone that also controls the metabolism of fatty acids and amino acids. Precise definition of new hormonal substances is difficult due to rapid progress in hormone biochemistry, physiology, and pharmacology. In classical endocrinology, hormones are defined as products that are synthesized by a group of cells (a hormone-producing organ), secreted into the bloodstream, and transported to their site of action (a hormone-responsive organ or tissue) where they exert specific effects. The hormone-producing organ is identified by the deficiencies observed after surgical removal of the source of hormone synthesis (endocrine gland). The hormone is characterized by isolation, structural analysis, and chemical synthesis; the deficiencies observed after removal of the endocrine gland are corrected by substitution. In this experimental approach, the biological effects of the hormone are used for its initial identification (bioassay) during purification from biological materials. Another source of information about hormones is clinical endocrinology [17]. The disease symptoms resulting from hormone deficiencies or hypersecretion provide a concept for the biological function of a particular hormone, and suggest methods for its bioassay. If the hormone is produced in cells disseminated throughout a nonremovable organ or at multiple sites in the body, a biochemical approach must be employed for identification of the hormone's physicochemical characteristics that can be exploited for its extraction and purification from normal tissue or endocrine tumors. Some tumors produce hormones in much larger quantities [23] than the physiological concentrations found in normal, nonneoplastic tissue.

The definition of hormones and regulatory factors will certainly change, classical hormones will no longer be defined as products associated only with specific endocrine glands, but will turn up in new unexpected locations and functions. Hormonal regulatory factors will acquire a more comprehensive role as endogenous substances secreted by many endocrine and nonendocrine cells. Their definition may then depend on regulation of cell activity rather than on their site of origin. The future classification of hormones may be based on assignment to chemical families, on interaction with receptors and intracellular effector systems, physiological and pharmacological effects, and localization in different tissues.

Classification of Hormones. Hormones can be classified according to their structural and biochemical similarities. This procedure is particularly useful because the wide distribution of hormonal substances in nonendocrine tissues makes it difficult to assign them to specific endocrine organs. Progress in structural analysis and isolation of natural compounds is rapid, especially as regards peptide and protein biosynthesis from genes expressed in different tissues and posttranslational processing to mature hormones [24]. Peptide and protein hormones and their precursors may be secreted directly into the bloodstream (*endocrine secretion*), released from nerve endings into specialized local vascular systems (*neuroendocrine secretion*), or secreted into the surrounding tissue (*paracrine secretion*).

A contemporary definition of hormones must include the peptides and amino acid derivatives (neurotransmitters) produced and secreted by specialized neuroendocrine and endocrine cells in the endocrine hypothalamus [14], the gastrointestinal tract [25], the right atrium of the heart [25], the endocrine pancreas [26], the thymus [27], and other organs not exclusively devoted to hormone secretion and synthesis. Neuroendocrine cells with a dual role of hormone secretion and neurotransmitter release are found in the adrenal medulla and sympathetic ganglia. Surprisingly, many hormone products that resemble the peptides of the central nervous system and the gastrointestinal hormones are found in the skin of amphibia.

Advances in structural elucidation, chemical synthesis, and specific detection methods (radioimmunoassay, immunohistochemistry, high-performance liquid chromatography) have disclosed a surprisingly wide dissemination of hormone-producing cells in tissues that were previously inaccessible to investigation by surgical removal and chemical substitution. The structural analysis of peptides, proteins, and their precursors by gene sequencing is progressing much more rapidly than the biological evalu-

ation of new hormone candidates. It is therefore helpful to discuss hormones according to their chemical and functional families rather than according to hormone-producing glands.

The most important chemical groups are the *steroid hormones* (Chaps. 3, 4, 5), [20] closely related to their common precursor, cholesterol, and the *peptide and protein hormones* [7] composed of amino acids which form chains of different length and conformation, frequently containing discrete subunits (→Peptide and Protein Hormones). The hormone group of *amino acid derivatives* (Chap. 2) comprises the *thyroid hormones*, and the hormonally active *catecholamines* and *indolamines*. The biogenic amines have multiple functions as hormones and neurotransmitters in the central and autonomous peripheral nervous systems. Hormone candidates are the *kinins* [12,28] and *prostaglandins* [29,30], which are a group of widely distributed endogenous substances with marked hormone-like activities.

1.1.2. Hormone-Producing Systems

Many hormones are integrated in complex regulatory systems. Their secretion may be activated or suppressed by hypothalamic and/or pituitary control, and the central regulation is in turn under the influence of feedback signals from peripheral hormone-responsive organs and tissues. Hormones with a homeostatic function maintain a constant internal environment by adaptation to changing external conditions (thyroid hormones and adrenal steroids). Hormones may be secreted throughout life if they are indispensable for metabolic activities (e.g., glucose- and calcium-regulating hormones), or at certain times of ontogenesis such as sexual maturation (gonadotropins and gonadal steroids).

Classical hormone-producing organs are the anterior and posterior pituitary gland, the thyroid gland, the parathyroid glands (epithelial bodies), the endocrine pancreas, the adrenal glands (adrenal cortex and adrenal medulla with chromaffin cells), the gonads, and the pineal gland. Destruction of these glands is associated with characteristic deficiency syndromes. Transient hormone-secreting organs also exist, e.g., the corpus luteum of the ovary and the placenta.

Site of Origin and Biosynthesis. To identify a hormone's site of origin, an endocrine gland is removed to study the resulting functional deficiencies and the effect of hormone substitution. More recent techniques to identify hormone-producing cells in non endocrine organs are immunohistochemistry and active immunization of animals against a hormone to neutralize its effects and define its function. Such studies sometimes disclose characteristic deficiency symptoms, but often fail due to compensatory mechanisms which replace the defective link [15].

Cells of common embryological ancestry may produce similar functional compounds even after their integration into nonendocrine tissues during ontogenesis. One hypothesis assigns a specific role to neuroendocrine Amine Precursor Uptake and/or Decarboxylation cells (APUD cells) which contain peptides and neurotransmitter-like amino acid derivatives. Such cells are widely found in the endocrine hypothalamus, anterior pituitary, parathyroid, and the gastrointestinal tract [31]. Biosynthesis of steroids is limited to the adrenal cortex. testes, and ovaries; the liver and kidneys metabolize steroid precursors to active calciferol derivatives. The thyroid hormones (thyroxine, triiodothyronine) are synthesized from monoiodotyrosine and diiodotyrosine. In the pineal gland, the hormone melatonin is synthesized from the precursor tryptophan. Remarkably, the placenta as a transient hormone-producing structure can synthesize peptides (e.g., LHRH, also called gonadorelin), proteohormones (e.g., HCG, human chorionic gonadotrophin), and steroid hormones (e.g., estrogens and progestins). Similarly, the corpus luteum of the ovary (a transient structure formed after ovulation) can secrete steroid hormones (estrogens and progestins), peptides (oxytocin), proteohormones (relaxin), and tissue hormones derived from arachidonic acid (prostaglandins).

Mode of Secretion. Many hormones are released directly into the bloodstream and reach their target organs over considerable distances. However, special modes of secretion also occur. Tissue hormones with direct (paracrine) action on neighbouring cells are secreted directly into the surrounding tissue and regulate cell-to-cell interaction. Some neurosecretory hormones (oxytocin, vasopressin) are transported to their

Figure 1. Hierarchy of hormone systems

site of storage in vesicles by axonal transport and released upon appropriate stimuli. The hypothalamic regulatory hormones reach the anterior pituitary gland (their target organ) by a special vascular pathway, the portal vessel system [14]. The pituitary gland is a composite, complex organ that consists of the anterior lobe (adenohypophysis), and a posterior lobe (neurohypophysis). The adenohypophysis contains several distinct cell types that secrete TSH, LH, FSH, growth hormone, prolactin, and corticotropin as well as proteohormones with presently undefined functions (endorphins, lipotropin, melanotropin). The posterior pituitary gland is a storage organ for two oligopeptide hormones, vasopressin and oxytocin that are synthesized in hypothalamic centers and transported to the posterior pituitary gland by axonal transport in neurosecretory cells, together with their binding proteins, the neurophysis.

The hierarchy of hormonal systems is summarized in Figure 1. Hierarchic hormone systems with two or three levels of control are regulated by hypothalamic hormones in the hypophysiotropic zone of the hypothalamus. These regulatory peptides activate or inhibit secretion of the anterior pituitary hormones. The *pituitary glandotropic hormones* (TSH, ACTH, FSH, LH) regulate their target tissues indirectly by hormone secretion of peripheral endocrine glands (thyroid and adrenal glands, gonads). The *pituitary effector hormones* (growth hormone, prolactin) act directly on target organs (Fig. 2), regulating proliferation and metabolism of peripheral

Figure 2. Secretion of pituitary hormones

tissues; in this respect they are similar to the calcium-regulating, glucose-regulating, and gastrointestinal hormones. Steroid hormones secreted by the gonads and adrenals act directly on target cells to induce specific proteins which regulate gene expression.

Control of Hormone Secretion. An important principle in the homeostatic regulation of body functions by hormones is their organization in hierarchic *feedback systems*, which may operate independently or in interdependence. Secretion of effector hormones is regulated by the feedback of their respective substrate (e.g., insulin by glucose, or parathormone by calcium). Secretion of glandotropic hormones is controlled by the feedback of their products (e.g., steroids) synthesized by the target organ. The serum concentration is monitored by hypothalamic and/or pituitary receptors. In the endocrine hypothalamus (hypophysiotropic zone), the secretion of regulatory factors (peptides and neurotransmitters) drives the endogenous rhythms of pituitary hormones [32]. The corticotropin releasing hormone (CRH) induces the secretion of ACTH (corticotropin), which has a marked diurnal rhythm with an early morning peak [33]. The gonadotropin releasing hormone GnRH, also known as gonadorelin or luteinizing hormone, LHRH) has a pulsatile circhoral rhythm which is reflected by pulsatile gonadotropin secretion, the amplitude and frequency of gonadotropin pulses being regulated by gonadal steroids [34]. The secretion of gonadotropin in a multiloop feedback system is summarized in Figure 3. The growth hormone releasing hormone (GHRH) activates the secretion of growth hormone (somatotropin), which has a marked endogenous sleep-associated rhythm closely coupled to rapid eye movement activity of the central nervous system [35]. Hormone secretion can also be controlled by neural regulation (e.g., prolactin by the suckling reflex of nursing), and is often modulated by the autonomous nervous system.

1.1.3. Structural Analysis and Synthesis

In hormone chemistry and biochemistry, the constraints of classical organ-related endocrinology are replaced by new concepts based on chemical, biochemical, and functional similarities, which take full advantage of modern methodology for identification of minute amounts of hormones, their precursors, and their metabolites in various tissues. New natural compounds (hormone candidates) can be identified by classical extraction, purification, and isolation followed by structural analysis and chemical synthesis, or by indirect structural analysis via gene sequencing, and biosynthesis by recombinant DNA technology. Their physiological and pharmacological functions must be established in biological studies.

Figure 3. Feedback regulation of gonadotropin secretion
The pituitary secretion of LH can act directly (short feedback) on the secretion rate. The testicular steroid secretion can also modulate gonadotropin secretion (long feedback). In the hypothalamic centers the LHRH pulsatility is controlled by the binding of gonadal steroids to receptive cell areas.

1.1.4. Receptors and Mechanisms of Action

Peptide and protein hormones act on specific receptors located in the cell membrane, whereas steroid hormones act on receptors located in the cytoplasm and cell nucleus. The formation of a hormone – receptor complex activates specific intracellular processes [13].

Membrane receptors for peptides and protein hormones are coupled to adenyl cyclase [36] or phospholipase as the intracellular effector system; they activate protein kinases, which regulate protein synthesis and the calcium permeability of the cell membrane and intracellular structures [37].

The binding capacity of receptors for peptides and protein hormones depends on the concentration of their ligand in the endocrine cells. The receptors are expressed upon physiological stimulation, their number increases with the ligand concentration (up-regulation), and declines when the physiological level of stimulation is exceeded. During supraphysiological stimulation, the receptor response is desensitized, and binding capacity is down-regulated (i.e., the number of receptors is reduced). The binding of hormone analogues with enhanced resistance to degradative enzymes often reduces the concentration of available receptors. Receptors are removed by enhanced coupling between receptors (microaggregation), followed by internalization of hormone – receptor complexes, and intracellular receptor degradation. Steroid hormones bind to intracellular (cytoplasmic or nuclear) receptors. The activated steroid-receptor complexes are translocated to the cell nucleus, where they regulate the synthesis of enzymes or functional proteins by means of gene expression [18, 38]. The binding capacity of the steroid hormone receptors is regulated in a dose-dependent manner. Steroid receptors are generally induced in the presence of their ligands and decrease with declining secretion of the relevant steroid.

1.1.5. Therapeutic Use of Hormones

Natural hormones provide valuable leads for structure – activity studies. Numerous steroid hormone analogues have been introduced into therapy, and synthetic analogues of peptides have also become valuable diagnostic and therapeutic aids. The larger proteins previously obtained by extracting biological material are now produced more economically by recombinant DNA technology [2] (→Genetic Engineering). The enhancement of specific biological activities or modification of the activity spectrum toward more desirable effects are the general aim of structure – activity studies.

1.2. Peptide and Protein Hormones

(→ Peptide and Protein Hormones)

1.2.1. Hypothalamic Hormones

The hypothalamic hormones comprise peptides which regulate anterior pituitary function (*neurohumoral mechanism*), and others (vasopressin and oxytocin) which are stored in the posterior pituitary and released upon demand (*neurosecretory mechanism*). Paracrine secretion of hormones into the surrounding tissue is the most ancient phylogenetic transmission principle. The neuroendocrine secretion of vasopressin and oxytocin is analogous to the more specific and effective transmission between nerve cells that involves the synaptic release of amine or peptide neurotransmitters. Vasopressin and oxytocin are synthesized in the hypothalamic neurosecretory cells and are transported along the cell axons to their storage vesicles in the posterior pituitary gland. The hormones are structurally similar nonapeptides that are stabilized by intramolecular sulfhydryl bridges. *Vasopressin* controls water reabsorption by the kidney and osmolality in the intravascular space. At pharmacological concentrations, vasopressin has marked cardiovascular effects (vasoconstriction and hypertension). Numerous vasopressin analogues have been synthesized to enhance antidiuresis, and to reduce hypertensive activity [39]. A second group of vasopressin agonists is used for the local control of bleeding by vasoconstriction. A central role for hormonally inactive vasopressin fragments has been postulated in the control of memory and learning. *Oxytocin* acts primarily on the contractility of smooth muscle of the uterus during parturition, and on the myoepithelium of the lactating mammary gland. Surprisingly, oxytocin has been identified in the ovary, but its physiological role in this organ is unknown. Detection of other established hormones in tissues where the occurrence was previously unknown is increasing due to improved microanalytical techniques.

1.2.2. Proopiomelanocortin Hormones

Peptides and proteins are generally synthesized as large prehormone molecules and processed to smaller active substances. A complex

hormone precursor found both in hypothalamic and anterior pituitary tissue gives rise to a family of opioid, corticotropic, and melanotropic peptides and proteohormones with diverse actions and functions [40–42]. The precursor, preproopiomelanocortin is processed to corticotropin (ACTH), melanotropin (MSH), lipotropins (LPH), enkephalins and endorphins.

Corticotropin (ACTH) is a linear polypeptide of 39 amino acids. This classical pituitary hormone is an interesting example of the post-translational processing of a precursor to form a highly active product. Structure – activity relations of ACTH analogues have been studied extensively [43]. The full corticotropic activity is expressed in the N-terminal amino acid sequence 1 – 24; the C-terminal sequence 25 – 39 does not contribute to biological activity. Corticotropin analogues with protected N- and C-termini significantly increase and prolong cortisol and aldosterone secretion in the adrenal cortex. They consist of 17 or 18 amino acids with enhanced enzyme resistance and a prolonged half-life for plasma elimination. ACTH (1 – 39) is secreted after hypothalamic stimulation of the corticotropin-producing cells by the corticotropin releasing hormone (CRH), a hypothalamic polypeptide of 41 amino acids [33]. This type of regulation of a small pituitary hormone by a slightly larger regulatory hormone is a surprising exception to the rule that hypothalamic hormones are small molecules which release several multiples of their own weight from the anterior pituitary gland (amplifier mechanism). Secretion of ACTH in the human has a characteristic peak in the early morning hours and can be reproduced by pulsatile injection of human CRH. There are clear indications for a dual control of ACTH by CRH and arginine – vasopressin. A similar redundant dual control system is found for mineralocorticoid secretion, aldosterone being secreted by the adrenal cortex after stimulation by both ACTH and angiotensin II. The latter is formed from angiotensinogen by the successive action of the enzymes renin and angiotensin converting enzyme (ACE). ACTH is a potent stimulator of the adrenal cortex, its hypersecretion by corticotropic pituitary adenomas can override the adrenal feedback completely. ACTH regulates biosynthesis of adrenal steroids from cholesterol via the intermediate Δ-5-pregnenolone [7]. It also has extraadrenal effects on pigmentary cells (melanotropic activity), and on mobilization of fatty acids from fat cells (lipolytic activity). When ACTH secretion is abolished by hypothalamic or pituitary lesions, the adrenal cortex rapidly involutes resulting in a characteristic hormone deficiency syndrome (Addison's disease) that is also observed after destruction of the adrenal cortex by tumors or infectious diseases. Excessive ACTH secretion results in marked melanotropin activity, inducing intense pigmentation of the skin.

Other polypeptides with significant sequence homologies to ACTH are also expressed on the proopiomelanocortin gene, namely α-, β-, *and* γ-*MSH.* These hormones have intense pigmentary activity in animals and humans. α-MSH is an N-terminal derivative that is acetylated by posttranslational processing. β-MSH is found as a circulating hormone in the human, but no physiological role has been established. The *lipotropins* [44] are of intermediate molecular mass (58 – 92 amino acids) and are also derived from the common ACTH – MSH precursor. Their physiological role is not fully established, they release free fatty acids from adipose tissue in vitro and in vivo. The *enkephalins* and *endorphins* (neuropeptides or peptide neurotransmitters) are regulators of central nervous activities, and of peripheral sensory functions such as perception of pain.

1.2.3. Glycoprotein Hormones

A group of pituitary hormones closely related by common subunits (an α-subunit and a hormone-specific β-subunit) comprises thyroid stimulating hormone (thyrotropin, TSH) and the gonadotropins follicle stimulating hormone (follitropin, FSH) and luteinizing hormone (lutropin, LH). The biological effects of these polypeptides are different despite extensive sequence homologies of their subunits. They undergo post-translational glycosylation after assembly of the α and β-subunits [45–48].

Thyrotropin. The secretion of thyrotropin (TSH) is under hypothalamic control of thyrotropin releasing hormone (TRH, protirelin), a tripeptide with protected N- and C-terminus. To a limited extent, protirelin also stimulates the release of prolactin (PRL) and is involved in other hypothalamic control systems for the release and

inhibition of prolactin secretion [14]. Numerous analogues of TRH have been synthesized with enhanced TSH releasing activity, or with significant neuropharmacological and cardiovascular effects but without endocrine activity [11]. TRH is useful in the diagnosis of thyroid function, but has not acquired a therapeutic role. Excess stimulation of TSH secretion by TRH can induce thyroid hyperplasia in animals, whereas human hyperthyroidism is generally caused by receptor-stimulating antibodies. Goiter formation in the human may result from disorders of thyroid hormone synthesis, which cause hypersecretion of TSH and proliferation of thyroid tissue. Human TSH has not found a therapeutic role, because thyroid hormone secretion is more easily substituted by synthetic thyroxin preparations.

Gonadotropins. The secretion of the gonadotropins FSH and LH is regulated by the hypothalamic luteinizing hormone releasing hormone (LHRH), also designated as the gonadotropin releasing hormone (GnRH). The decapeptide LHRH is used for diagnosis and therapy of infertility. With an intact pituitary gland, pulsatile infusion of LHRH stimulates gonadotropin secretion. This provides a method for treating human hypogonadotropic hypogonadism and is an alternative to gonadotropin preparations. Numerous agonists and antagonists of LHRH have been synthesized [9,49] to control gonadal steroid secretion in diseases such as endometriosis, uterine leiomyoma, and steroid-dependent tumors (prostate and mammary carcinoma). The LHRH agonists induce persistent receptor desensitization and selective inhibition of gonadotropin secretion during daily high dose injections or continuous release from implants. The LHRH antagonists have similar inhibitory pharmacological effects on gonadal steroid secretion although their mechanisms of action are clearly different.

The gonadotropins are glycoproteins with about 180 amino acids, and multiple glycosylation sites [46,50]. Follitropin (FSH) stimulates estrogen secretion from ovarian follicles and prepares them for subsequent induction of ovulation by lutropin (LH). LH has ovulatory activity and enhances ovarian steroidogenesis in synergy with FSH, in particular the secretion of progesterone by the corpus luteum after ovulation. In men, spermatogenesis is dependent on FSH, which acts on the germinal epithelium in synergy with LH and testosterone. LH stimulates the interstitial cells of the testes to secrete testosterone and small quantities of estrogens.

In animals and humans, FSH and LH are excreted in the urine; similar gonadotropins have been extracted from the serum of pregnant animals (pregnant mare's serum gonadotropin, PMSG). These urinary gonadotropins have been extensively studied, and are used for therapy. Urinary gonadotropins with high FSH- and LH-activities can be extracted from the urine of postmenopausal women for the stimulation of follicular maturation in infertile women (human menopausal gonadotropin, hMG).

1.2.4. Growth Hormone, Prolactin, and Placental Lactogen

Extensive structural homology is found between pituitary growth hormone (GH, somatotropin), pituitary prolactin (PRL), and human placental lactogen (hPL, see under Section 1.2.5). GH and prolactin contain 191 and 198 amino acids, respectively [51]. Both hormones have been extracted from human and animal pituitary glands, but only growth hormone has become a valuable therapeutic agent. It is produced by recombinant DNA biosynthesis to avoid contamination with the neurotropic virus found in human pituitary tissue [52].

The amino acid sequence of *growth hormone* has marked species specificity [53,54], therefore substitution therapy in children should only be performed with human growth hormone (hGH) to avoid antibody formation and loss of efficacy. The plasma elimination half-life of injected growth hormone is about 20 min. Growth hormone has many effects on metabolism (e.g., increased glucose utilization and lipid mobilization) and a marked anabolic effect on amino acid transport into cells and subsequent protein biosynthesis. Treatment with hGH can correct growth deficiency and short stature in children provided that epiphyseal closure of the bones has not occurred. Appropriate species-specific GH can also induce growth in farm animals. Many of the metabolic effects of GH are mediated by inducing the synthesis of growth factors [4], particularly the somatomedins. The GH-dependent somatomedins stimulate the formation of new cartilage; increased incorporation of sulfate into

newly formed cartilage (sulfation factor) is a sensitive bioassay. During lactation, growth hormone acts in synergy with sexual steroids and prolactin on milk production. Hypersecretion of GH in acromegaly is manifested by pathological growth of the hands and feet, facial skeleton, enlargement of the skull, and heart, frequently followed by cardiac insufficiency.

Despite marked sequence homology with growth hormone, the growth-inducing activities of prolactin (PRL) and human placental lactogen (HPL) are negligible. *Prolactin* contributes to the maintenance of corpus luteum function in animals, and stimulates milk production during lactation, in synergy with GH and sexual steroids. Prolactin secretion appears to be under dual hypothalamic inhibitory control effected by release of dopamine [55] and specific peptide factors (prolactin inhibiting factor, PIF) into the pituitary portal vessels. Hypersecretion of PRL is found in pituitary micro- and macroadenoma. The insufficient endogenous inhibition of PRL secretion by endogenous dopamine can often be remedied by using potent dopamine agonists [56].

1.2.5. Placental Hormones

The placenta secretes structural homologues of TSH, FSH, LH, GH, and prolactin. A placental gonadotropin, human chorionic gonadotropin (choriotropin, hCG), is extracted from urine of pregnant women in large quantities for therapy of infertility; it is a glycoprotein that is similar to FSH and LH [57]. Other placental proteins (human placental lactogen and a TSH-like glycoprotein) have not found therapeutic applications [51]. Numerous oligopeptides occur in placental tissue, but are apparently not secreted during pregnancy.

1.2.6. Calcium-Regulating Hormones

There are two groups of calcium regulating hormones, the rapidly acting polypeptides calcitonin and parathormone (PTH), and the slowly acting steroids (calciferols, see Chap. 5). The polypeptides allow rapid adjustment of the serum calcium concentration to physiological reguirements. *Calcitonin* is a species-specific polypeptide of 32 amino acids (M_r 3700); salmon and chicken calcitonin are among the most potent natural calcitonins [58]. The hormone is synthesized in the parafollicular C cells of the human thyroid gland, and in the ultimobranchial gland of several species of fish. Calcitonin lowers elevated serum calcium and phosphate levels, inhibits the activity of osteoclasts (cells inducing the resorption of bone), decreases renal reabsorption of calcium and phosphate ions, and decreases absorption of calcium from the gastrointestinal tract. Calcitonin acts on specific peptide receptors in the bone, repeated administration causes progressive receptor desensitization. In the brain, a calcitonin-gene related peptide is found with unidentified central regulatory effects [24]. Calcitonin has analgesic effects, which may be mediated by brain and spinal cord receptors.

The physiological antagonist of calcitonin, *parathormone* (PTH) is a species-specific polypeptide of 84 amino acids; the N-terminal 34 amino acids are required for full biological activity [59]. Parathormone is synthesized in the parathyroid cells (epithelial bodies), which in the human are found close to the thyroid gland. The effects of PTH include rapid mobilization of calcium from the bone matrix by activation of osteoclasts, activation of phosphate excretion by the kidney via inhibition of reabsorption, concomitantly increased renal excretion of calcium, and enhanced absorption of calcium from the gut. Endocrine-active tumors may secrete parathormone and induce hypercalcemia, which responds rapidly to calcitonin injections.

1.2.7. Cardiovascular Hormones

Three groups of peptides contribute to the regulation of blood pressure and intravasal volume: the angiotensins, the atrionatriuretic peptide (ANP), and the kinins [12]. Marked vasoconstriction and blood pressure increase is found after the stimulation of angiotensin I production. Angiotensin I is a nonapeptide that is produced from the precursor angiotensinogen by the enzyme renin. Renin is secreted by the juxtaglomerular kidney cells upon reduction of the glomerular filtration rate and hypoxia. Angiotensin I is converted to the octapeptide angiotensin II by the angiotensin convert-

ing enzyme (ACE). Numerous angiotensin antagonists have been synthesized as antihypertensive (blood pressure-lowering) peptides, but all have intrinsic vasoconstrictor activity. Angiotensin antagonists can be used to diagnose angiotensin-induced hypertension because they competitively inhibit the increased angiotensin concentrations found after renal artery occlusion. The di- and tripeptide ACE inhibitors captopril and enalapril, are used for the long-term therapy of hypertension; they have found great importance due to their high efficacy after oral absorption.

The *atrionatriuretic peptide* (ANP) is a functional antagonist of angiotensin II. It occurs in the right atrium of the heart and is released upon acute dilatation of the right atrium [60, 61]. ANP is synthesized as a preprohormone complex of 152 amino acids, and post-translationally cleaved to an active peptide containing 28 amino acids. ANP agonists consisting of peptides containing 22 or 23 amino acids are available; they have markedly enhanced vasodilatory and blood pressure-lowering activity, as well as acute and sustained stimulatory effects on sodium excretion and urinary flow rate.

The *kinins* are also physiological antagonists of angiotensin and are found in many tissues. They are nona-, deca- or undecapeptides that are released by the enzyme trypsin from the α-globulin fraction of serum [12]. All kinins are potent vasodilators; they lower blood pressure acutely, increase capillary permeability, and rapidly induce local tissue reactions characterized by edema, pain, and acute inflammation. The kinin peptides cause contraction of smooth muscle in the intestinal tract and the uterus. They can be secreted in significant quantities by endocrine-active tumors of the gastrointestinal tract. Many bradykinin-derived peptides have been studied without confirmation of therapeutic usefulness.

1.2.8. Glucose-Regulating Hormones

The protein hormones insulin and glucagon have vital effects on energy metabolism, cell permeability, and the homeostasis of cell function. Insulin and glucagon are the most important physiological factors in the control of cellular glucose concentrations; however, other hormones (e.g., growth hormone, glucocorticoids and somatostatin) also have significant effects. Insulin is used for substitution therapy of diabetes mellitus; glucagon is employed very infrequently.

Insulin is a polypeptide of 51 amino acids. It contains an α- and a β-chain that are synthesized as part of a larger precursor molecule of 84 amino acids (proinsulin). After post-translational removal of the connecting peptide from proinsulin, the two chains are joined by disulfide bonds [3]. Insulin is stored in the β-cells of the pancreas as a hexameric zinc-containing complex. The main action is to regulate cell permeability to glucose and potassium. The primary sequence of insulin is species-specific, but the biological action of human and animal insulins are similar. Porcine insulin is most closely related to human insulin. Human insulin can be obtained from porcine insulin by removing the eight N-terminal amino acids and replacing them with the corresponding human sequence. Human insulin has a plasma elimination half-life of about 20 min after intravenous injection. Numerous derivatives and pharmaceutical formulations have been developed to prolong the action of insulin by delayed absorption and sustained release from the subcutaneous injection site. Insulin pumps can deliver insulin according to a preset daily program; nasal administration of insulin is also being studied. The chemical synthesis of insulin has been described [6], but human insulin produced by recombinant DNA technology is now gradually replacing the previous porcine and bovine insulin preparations. Numerous structure activity studies have been performed with insulin analogues but they are not used in clinical medicine [6].

The physiological antagonist of insulin is *glucagon* [22], a linear polypeptide of 29 amino acids (M_r 3500). The biosynthesis of glucagon proceeds via a large preprohormone. The pancreatic β-cells contain biologically active glucagon and two glucagon-related peptides of unknown physiological significance. The gut contains an inactive precursor form of glucagon (glicentin). Glucagon is released from the pancreas upon a decrease in the blood-glucose concentration and stimulates gluconeogenesis. Its plasma elimination half-life is short (ca. 5 min). Glucagon has a strong inotropic action (i.e., enhances myocardial contractility). In contrast to insulin, glucagon has not acquired an important

therapeutic role, although some of its pharmacological effects at higher doses have been widely studied.

1.2.9. Gastrointestinal Hormones

Numerous peptides and proteins with established or possible hormonal function are found in the salivary glands, stomach, duodenum, ileum, and colon. These gastrointestinal hormones influence acid and bile secretion, digestive enzyme production, and gastrointestinal motility [5,10,25,62]. *Tissue hormones* such as kinins and neurotensin have been isolated from the salivary glands, but their physiological role is doubtful [12]. In the stomach, *gastrin* is found in three different molecular forms with 13, 17, and 34 amino acids [16]. It is an N-terminally processed peptide whose biological activity (stimulation of acid secretion in the stomach) is associated with its C-terminal 14 – 34 sequence. Gastrin has extensive sequence homology with the C-terminal active sequence of *cholecystokinin* (CCK), which is synthesized in the cells of the duodenal mucosa. Cholecystokinin stimulates contraction of the gall bladder and release of bile into the duodenum; it also enhances the secretion of pancreatic enzymes. The biological activity of CCK is attributed to a linear sequence of 33 amino acids (M_r 3883). Several smaller C-terminal forms of CCK are found in the duodenum and in central nervous tissue [63]. The central role of CCK fragments may be in the control of appetite as a satiety signal. Another duodenal hormone is *secretin*, a linear polypeptide with 28 amino acids (M_r 3000). Secretin stimulates the release of bicarbonate-rich pancreatic fluid which neutralizes the acid gastric juice when it reaches the duodenum. Secretin has significant sequence homologies with glucagon and other gastrointestinal peptides such as the vasoactive intestinal polypeptide and gastrointestinal polypeptide. *Motilin* is a further gastrointestinal polypeptide (22 amino acids) which stimulates gastric motility. Tumors of the gastrointestinal tract may contain and secrete a large variety of hormonally active peptides, e.g., growth hormone releasing hormone (GHRH) and its fragments, somatostatin, vasoactive intestinal peptide, and gastrin [5].

1.2.10. Growth Factors and Related Peptides

The growth requirements of cultured cells have been studied extensively. Specific growth factors appear to be involved in cell replication, physiological tissue repair, and pathological tumor growth [4]. Their secretion may be activated by human oncogenes and viruses [64].

The growth factors are produced by the tissues in response to growth hormone and other hormones. For example, the *somatomedins* are produced in response to the action of growth hormone; and *the estromedins* in response to the action of estrogens [65]. Numerous closely related groups of factors have been described such as the nerve growth factors [4], the epidermal growth factor and transforming growth factor alpha, the basic and acidic fibroblast growth factor [66], the endothelial cell growth factor [67], the platelet-derived growth factor, and the transforming growth factor beta [68]. The hormonal roles of these regulatory polypeptides are not clearly established because they have many pharmacological effects in vitro, and definition of their physiological functions is difficult.

1.2.11. New Hormonal Peptides and Proteins

The rapid progress of indirect structural analysis by gene sequencing and recombinant DNA technology has resulted in characterization and biosynthesis of many new hormonal factors. An example is *erythropoietin*, a glycoprotein found in the kidney which stimulates erythrocyte production [69] and hemoglobin synthesis. Local ovarian hormones have been identified such as relaxin [70,71], and the Muellerian-inhibiting substance (MIS). The MIS is a glycoprotein of 300 – 350 amino acids that is synthesized as a preprohormone of 560 amino acids but its hormonal role is difficult to assess [72]. It controls the development of the male phenotype by suppressing development of the (female) Muellerian duct during embryonal differentiation. The MIS may have a pharmacological use to suppress proliferation of ovarian and endometrial tumors. Another ovarian protein regulates FSH secretion in vitro and in vivo. It consists of two subunits, which may associate to form either an FSH-inhibiting heterodimeric protein (*inhibin*) or an FSH-releasing homodimeric protein (*activin*) [73,74].

1.3. Amino Acid Derivatives

The catecholamines, indolamines, and the more complex thyroid hormones are amino acid derivatives.

1.3.1. Catecholamines and Indolamines

Catecholamines have a dual role as cardiovascular and stress hormones. They are found in the chromaffin cells of the adrenal medulla and in sympathetic nerve endings; they also act as neurotransmitters in the central nervous system. *Noradrenaline* (norepinephrine) and *adrenaline* (epinephrine) are neurotransmitters that control hormone secretion by modulating the endocrine activity of the hypothalamus and pituitary gland. They are also involved in the central and peripheral regulation of blood pressure, and in the modulation of metabolic functions by the autonomous nervous system [75]. The most important indolamine is *melatonin*, a substance found in the pineal gland of animals and humans [76–78]. Melatonin inhibits sexual development in young animals before puberty (antigonadotropic hormone), its function in adults is not known.

1.3.2. Thyroid Hormones

The thyroid hormones thyroxine (3,5,3′,5′-tetraiodothyronine, T_4, and 3,5,3′-triiodothyronine, T_3) are iodinated derivatives of thyronine and are formed by oxidative coupling of the precursors 3-monoiodotyrosine and 3,5-diiodotyrosine. Thyroid-specific enzymes are responsible for the iodination of tyrosine. Numerous thyroid hormone analogues have been synthesized but do not have practical benefits for therapy [79]. Thyroxine (T_4) is stored in the thyroid follicles in the form of thyroglobulin (a glycoprotein with iodinated tyrosyl residues). The thyroid stimulating hormone (TSH) from the anterior pituitary stimulates release of thyroxine into the blood stream. Thyroxine serves both as a direct stimulator of metabolic activity, and as a prohormone for its more active metabolite, thyronine (T_3). The thyroid hormones regulate the adaptation of body temperature and metabolic rate to exogenous conditions. The pituitary – thyroid system is largely independent of hypothalamic activation and can function in animals with brain lesions that eliminate endogenous TRH secretion. Several synthetic compounds that inhibit the biosynthesis of thyroid hormones have been found, they act primarily by inhibiting thyroid hormone iodination, or by restricting the uptake of iodine into the thyroid gland [75].

1.4. Steroid Hormones

Steroid hormones share cholesterol as their common precursor [18, 20] and can be divided into three main physiological groups: the *gonadal steroids* produced in the ovary (estrogens and progestins) and testis (androgens), the *adrenal steroids* produced in the adrenal cortex (glucocorticoids and mineralocorticoids), and the *calcium-regulating sterols* (calciferols). The calcium-regulating calciferols [80], derivatives of 7-dehydrocholesterol and ergosterol, are activated by hydroxylation in the liver (25-hydroxycalciferol) and in the kidneys (1,25-dihydroxycalciferol and 24,25-dihydroxycalciferol).

There are three structural groups, the C-21, C-19, and C-18 steroids.

1.4.1. Gonadal Steroids

The most important C-21 gonadal steroid is *progesterone*, which is secreted in large amounts by the corpus luteum and the placenta. The most important C-19 gonadal steroid is *testosterone*, which is responsible for the secondary sex characteristics in the male and supports spermatogenesis in synergy with follicle stimulating hormone (FSH). *Estrogens* are C-18 gonadal steroids that are secreted in large quantities by the developing ovarian follicles, and in small quantities by the Leydig cells of the testis. Natural estrogens, progestins, and androgens are of little use for therapy because of poor gastrointestinal absorption and insufficient duration of action. Since 1930 many groups of workers have synthesized steroid hormone analogues to obtain synthetic hormones with improved therapeutic properties for the control of pituitary function (steroid inhibition of estrogen or androgen secre-

tion by gonadotropin suppression), for substitution therapy in deficiency syndromes such as hypogonadism or after the menopause, and particularly for the control of ovulation (contraceptive steroids). In general, the pharmacological activity of synthetic gonadal steroids is never limited to interaction with a particular type of receptor (i.e., estrogenic, androgenic, progestagenic, glucocorticoid, or mineralocorticoid); instead, the spectrum of biological and pharmacological activities is dose-dependent. For example, some synthetic C-19 steroids have a high progestagenic potency, but frequently retain androgenic effects. The synthetic estrogen 17-ethinylestradiol displays high oral absorption due to its low metabolic inactivation and has become a major component of oral contraceptives. Stilbene compounds are highly active nonsteroidal estrogenic substances with high oral absorption rates. Steroidal and nonsteroidal receptor antagonists have also been developed which competitively inhibit the receptor binding and the biological effects of natural androgens, estrogens, and progestins [9]. Of particular importance are the steroidal antiandrogen cyproterone acetate and the nonsteroidal antiandrogen flutamide. In treatment of postmenopausal mammary carcinoma, the partial antiestrogen tamoxifen is most widely used [9]; nonsteroidal antiestrogens are in development. The pharmacological activities of synthetic gonadal steroids have been reviewed extensively [19]. Work is aimed at developing new specific receptor antagonists (antiprogestins), and steroids with novel therapeutic activities (e.g., inhibitors of aromatase and 5-α-reductase).

1.4.2. Adrenal Steroids

The adrenal cortex contains glucocorticoids (cortisol and cortisone) and mineralocorticoids (aldosterone and desoxicorticosterone). These C-21 steroids [7] are of particular importance because of their life-supporting activity in substitution therapy of adrenal insufficiency.

The *glucocorticoids* regulate gluconeogenesis from amino acids, and serve as stress-adaption hormones. Their medical importance is due to the strong antiinflammatory and immunosuppressive potential. The glucocorticoids are synthesized in the zona fasciculata of the adrenal cortex and their diurnal pattern of secretion is closely linked to that of ACTH (corticotropin). Feedback between the adrenal steroids and the pituitary secretion of ACTH is very effective. During long-term therapy with synthetic glucocorticoids, endogenous ACTH secretion is often suppressed, and may result in reversible adrenal involution or irreversible adrenal atrophy. At higher doses, the glucocorticoids suppress the tissue reaction to inflammation, reduce cell division in the bone marrow and lymphopoetic tissues (thymus gland and lymph nodes), and acutely inhibit exudation by reducing capillary permeability. This pharmacological activity is of importance in the treatment of acute kidney disease because it suppresses pathological permeability of the glomerular filtration system for proteins, and prevents progressive loss of albumin. Glucocorticoids have catabolic and antianabolic activities, they enhance protein catabolism and gluconeogenesis, and mobilize calcium by lowering the anabolic stimulation of bone formation anc bone mineralization. Under glucocorticoid therapy, calcium is lost from bones resulting in steroid-induced osteoporosis.

The *mineralocorticoids* regulate water and electrolyte metabolism by enhancing the renal reabsorption of sodium and water, and the excretion of potassium and hydrogen ions. The most important mineralocorticoid in the human is aldosterone (sodium-retaining hormone), which increases sodium reabsorption in the distal tubule of the kidney. Together with vasopressin it also regulates the osmolarity and ionic composition of the intravascular space. Enhanced secretion of aldosterone by adrenal tumors may lead to hypertension. In cardiovascular disease and hepatic failure, circulating aldosterone may be elevated (secondary aldosteronism) stimulating the formation of edema due to pathological sodium retention. Specific receptor antagonists of aldosterone (spironolactones) are used in therapy to counteract the sodium-retaining effect [9].

1.4.3. Calciferols

The calciferols (calcium-regulating sterols) are secosteroids with an opened ring B (between C 9 and C 10) derived from 7-dehydrocholesterol or ergosterol. They have a significantly delayed

onset of action because they induce intestinal calcium-binding proteins [80] by interaction with the genome, they also metabolize calcium and phosphate from the bone to provide a higher concentration in the extracellular fluid for osteoid mineralization.

1.4.4. New Synthetic Steroid Hormones

Progress in the development of synthetic steroid hormone analogues has resulted in new possibilities for the specific control of reproductive function. Receptor antagonists of progesterone have been developed for clinical studies on postcoital contraception by reducing or blocking corpus luteum formation [9]. These compounds also inhibit the action of cortisol and may stimulate the immune system by neutralizing the immunosuppressive effects of glucocorticoids.

1.5. Prostaglandins

The prostaglandins are endogenous compounds with hormone-like activities that all have the prostanoic acid skeleton and share arachidonic acid as their common precursor [29,30]. They influence the regulation of blood flow, kidney function, and hormone secretion. For a detailed description, see →Prostaglandins.

Prostanoic acid

Prostaglandin analogues of the E- and F-series have marked biological activities on reproductive functions, they lower progesterone secretion from the corpus luteum, and increase uterine contractility during pregnancy, and at parturition. Their multiple effects and sites of action make the clear assignment of classical hormonal functions very difficult, they should therefore be viewed as hormone candidates. In contrast to many peptides, proteins, and steroids which can be administered systemically without major tolerance problems, the prostaglandins are more difficult to handle because of their wide spectrum of activities that often includes severe side effects.

1.6. Hormone Antagonists and Analogues

Functional or competitive hormone antagonists (antihormones) can be divided into several groups with different modes of action [9]. The competitive receptor antagonists displace hormones from their receptors, and prevent physiological receptor activation by endogenous hormones. Such antagonists may be structurally related to the natural ligand (e.g., LHRH antagonists), or structurally unrelated, but of similar three-dimensional conformation (e.g., nonsteroidal antiandrogens). The noncompetitive inhibitors of hormone secretion often interfere with biosynthesis. They can act at a multitude of sites, as shown by the antithyroid drugs [75], the inhibitors of adrenal steroid secretion, aminoglutethimid and mitotan [9], and the inhibitor of gonadal and adrenal steroid biosynthesis, ketoconazole [9]. Future developments in drug design will be based on computer modeling of the active sites of hormone receptors, and of the three-dimensional conformation of synthetic hormone analogues capable of interacting with these receptors. Examples for nonsteroidal compounds interacting with steroid receptors are numerous, whereas similar developments are rare in the peptide and protein field, with the exception of structural similarities between opiates and endogenous opioid peptides [81], the encephalins and endorphins. There are until now no examples of nonpeptide drugs capable of blocking peptide receptor binding.

The concept of using natural hormones as lead compounds for synthetic modification by structure – activity studies has been particularly successful. Gonadal and adrenal steroids have been modified by chemical synthesis to obtain more potent compounds with enhanced metabolic resistance, specific receptor antagonists with selective inhibitory potential, and nonsteroidal compounds with simplified structures. The development of new steroidal and nonsteroidal molecules with improved biological and therapeutic characteristics is still in progress; there are indications for selective antiprogestins and antiglucocorticoids [9]. In the field of peptides and proteins, significant progress is being made by the widespread application of molecular biology and genetic engineering. Structural

analysis of polypeptides and proteins by gene sequencing has afforded many new lead compounds which can be studied by recombinant DNA synthesis in bacteria, yeast, or mammalian cell lines [2]. The availability of these biosynthetic molecular probes may initiate structure–activity studies on highly selective and specific synthetic peptide hormones. The receptor binding of new synthetic hormone derivatives, and an understanding of the mechanisms of action of natural hormones has been crucial for a more effective approach to drug design. Homogeneous receptor proteins for peptides and steroids are sequenced and synthesized in genetic engineering. The understanding of the molecular basis of cellular activation is increasing, and the mechanisms of action of peptide, protein, and steroid hormones are becoming more transparent.

2. Amino Acid Hormones

2.1. Thyroid Hormones

The thyroid hormones are produced in the thyroid gland, an endocrine gland located in front of the trachea and below the larynx, which consists of two lobes, connected by an isthmus. The thyroid gland stores ingested iodine in the follicular cells and secretes the thyroid hormones thyroxine (L-tetraiodothyronine) and triiodothyronine into the blood, as required. These two iodinated amino acid derivatives affect metabolism in a variety of ways. They not only regulate energy turnover, water balance, and the metabolism of carbohydrates, proteins, fats, and minerals, but also affect growth and maturation.

In addition, the parafollicular C cells of the thyroid produce another type of hormone, calcitonin, a peptide hormone, which participates in the regulation of calcium metabolism. However, the exact physiological function of this hormone is not yet known. Another peptide hormone, parathormone, which also influences calcium metabolism, is secreted by the parathyroid glands.

2.1.1. Physiology and Therapeutic Uses

Biosynthesis of Thyroid Hormones. The healthy thyroid gland takes up approximately 75 µg of iodine per day, provided enough dietary iodine is available (150 – 300 µg/d). Iodine is used to iodinate the tyrosine residues of a thyroid-specific protein *thyroglobulin*. The resulting 3,5-diiodotyrosine groups in the peptide chain of thyroglobulin react with each other or 3-monoiodotyrosine to form thyroxine (3,5,3′,5′-tetraiodothyronine) or triiodothyronine, respectively. This thyroxine- and triiodothyronine-containing thyroglobulin is stored in the colloid within the thyroid follicle. The normal human thyroid contains approximately 10 mg of iodine in this form. During secretion, thyroglobulin leaves the colloid and is hydrolyzed by the surrounding follicular cells. The liberated hormones, thyroxine (T_4) and triiodothyronine (T_3), are released into the blood at rates of ca. 100 and 8 µg/d, respectively.

The thyrotropic hormone of the pituitary hypophysis (thyrotropin or thyroid-stimulating hormone, TSH) stimulates the secretory function of the thyroid gland. The hypophyseal secretion of TSH, in turn, is stimulated by the hypothalamic hormone TRH (thyrotropin-releasing hormone; see also →Peptide and Protein Hormones) and inhibited by elevated levels of blood T_4 or T_3 in a feedback mechanism. In the blood, T_4 and T_3 are bound to serum proteins, principally thyroxine-binding globulin. Only 0.03 % of T_4 and 0.3 % of T_3 are present in the free (physiologically active) form. The biological half-life of T_3 is only ca. 19 h, whereas that of T_4 is ca. 190 h. Further formation of T_3 (approximately 30 µg/d) occurs in the peripheral tissues as a result of the deiodination of T_4. Because T_3 has approximately ten times the biological activity of T_4, thyroxine is considered to be the prohormone of the biologically more active triiodothyronine [87]. In addition to T_3, a second isomeric iodoamino acid, reverse T_3, (L-3,3′,5′-triiodothyronine, rT_3) is formed from T_4 in the periphery but has no apparent physiological activity [88].

Effect of Thyroid Hormones. Free thyroxine and especially free triiodothyronine probably bind to the nuclear and mitochondrial receptors, thereby activating protein synthesis or adenosine triphosphate production, respectively. The primary effects of the thyroid hormones are

1) stimulation of carbohydrate turnover, growth, and maturation in the central nervous system, skeletal and muscular systems, and genital organs; stimulation of heat production, oxygen consumption, cholesterol metabolism, turnover of free fatty acids, muscle contraction, heart rate, and cardiac output; and
2) inhibition of glycogen and protein synthesis (only at nonphysiological concentrations).

The amount of thyroid hormones required by the human organism varies between 50 and 300 µg/d, depending partly on the individual metabolism.

Thyroid Diseases. Thyroid diseases can affect the morphology (goiter, nodules, carcinoma) or the function (hyperthyroidism, hypothyroidism) of the thyroid. In many cases, thyroidal autoantibodies or iodine deficiency is the cause of the thyroid disorder. Hyperthyroidism is characterized by tachycardia, sweating, weight loss, diarrhea, etc. Hypothyroid children show abnormal physical and mental development. Hypothyroid adults tend to react slowly or to be depressed; additional symptoms are dry skin, obstipation, and sensitivity to cold.

Diagnosis. Diagnosis of thyroid disease is based not only on clinical symptoms but also on the measurement of serum concentrations of T_4, T_3, and TSH (basal or stimulated by the addition of TRH, i.e., the TRH test) and, if necessary, on thyroid uptake, iodine turnover, and the functioning of the hypophysis – thyroid feedback control system.

Therapy with Thyroid Hormones. (See also →Thyrotherapeutic Agents). Diseases of the thyroid gland that involve a thyroid hormone deficiency can be treated easily and successfully by oral administration of thyroid hormones. Treatment with levothyroxine is preferred because of the long half-life of this hormone. The sodium salt of levothyroxine in tablet form is absorbed to the extent of 40 – 60 % [89, 90], or 70 – 85 %, depending on the galenic preparation [91]. The daily dose of levothyroxine varies between 50 and 300 µg, depending on the severity of thyroid deficiency. The daily dose of liothyronine is correspondingly lower (10 – 100 µg). Injectable thyroid hormone solutions are used in cases of severe hypothyroidism (myxedema coma). Preparations containing both thyroid hormones are also available. Treatment with thyroid gland powder is no longer recommended because the standardization and stability of these preparations are problematic.

Therapy with thyroid hormones is sometimes recommended in certain types of obesity. Both dextrothyroxine (4 – 10 mg/d) and dextrotriiodothyronine (0.5 – 2 mg/d) are used in the treatment of disorders of fat metabolism, particularly hypercholesterolemia. L-Diiodotyrosine is also administered clinically; however, this preparation functions primarily as an iodine carrier because it is rapidly metabolized.

A number of analogues and derivatives of thyroid hormones have been synthesized and studied. Although substances with many times the thyromimetic activity of levothyroxine have been produced [92], none has found practical use. Triiodothyroacetic acid [*51-24-1*] (TRIAC), a degradation product of the thyroid hormones, occurs only in small amounts in the human body and exhibits a TSH-suppressing effect without the peripheral effects of levothyroxine or liothyronine. This compound has been successfully used in the treatment of hyperthyroidism caused by hypophyseal TSH-producing tumors [93].

2.1.2. Physical Properties

Levothyroxine [*51-48-9*] (L- 3,5,3′,5′-tetraiodothyronine, T_4), $C_{15}H_{11}O_4I_4N$, M_r 776.87, *mp* 235 – 236 °C (decomp.), $[\alpha]_D$ +20.4° (2 % solution in a 1 : 4 mixture of HCl and ethanol), $[\alpha]_D$ −5.8° (3 % solution in a 1 : 2 mixture of 1 mol/L NaOH and ethanol), forms colorless, light-sensitive crystals. It is sparingly soluble in water, slightly soluble in methanol, and readily soluble in alkali or dilute mineral acids.

The sodium salt of levothyroxine [*25416-65-3*] crystallizes from a hot solution of the free acid in sodium carbonate: $C_{15}H_{10}O_4I_4NNa \cdot 5\,H_2O$, M_r 888.94 [94, p. 476], [95, p. 642].

Liothyronine [*6893-02-3*] (L- 3,5,3′-triiodothyronine, T_3), $C_{15}H_{12}O_4I_3N$, M_r 650.98, *mp* 233–234 °C, $[\alpha]_D^{24}$ +23.6° (5 % solution in a 1 : 2 mixture of 1 mol/L HCl and ethanol), forms colorless crystals. It is slightly more water-soluble than thyroxine and readily soluble in dilute alkali [94, p. 268], [95, p. 643].

Reverse T_3 [*5817-39-0*] (L-3,3′,5′-triiodothyronine, rT_3) $C_{15}H_{12}O_4I_3N$, *mp* 206 °C (decomp.), $[\alpha]_D^{21}$ +16.7° (1 % solution in a 1 : 1 mixture of 1 mol/L HCl and ethanol), forms colorless needles [96].

l-3,5-Diiodothyronine [*1041-01-6*] (T_2), $C_{15}H_{13}O_4I_2N$, M_r 525.08, has the following properties: *mp* 254 °C (decomp.), $[\alpha]_D^{25}$ +25.2° (5 % solution in a 1 : 2 mixture of 1 mol/L HCl and 95 % ethanol).

l-3,5-Diiodotyrosine [*66-02-4*] (DIT, iodogorgoic acid), $C_9H_9O_3I_2N \cdot 2\,H_2O$, M_r 469.02, *mp* 204° (decomp.), $[\alpha]_D$ +2.75° (4.8 % solution in 1 mol/L HCl [97]), has the following structure:

l-3-Iodotyrosine [*70-78-0*] (monoiodotyrosine, MIT), $C_9H_{10}O_3IN$, M_r 307.09, has the following properties: *mp* 204–206 °C, $[\alpha]_D^{22}$ −8.8° (4 % solution in 1 mol/L HCl).

The corresponding D-isomers of the above iodoamino acids are also known. Dextrothyroxine is used therapeutically to lower cholesterol levels.

2.1.3. Production

In the thyroxin synthesis, first performed in 1927, 4-(4-methoxyphenoxy)-3,5-diiodonitrobenzene was converted into the corresponding aldehyde and then into D,L-diiodothyronine, which was iodinated to yield thyroxine [98]. This method was used commercially for a long time and produced a racemate. Resolution of the racemates of thyroxine has not yet been achieved.

The natural hormones levothyroxine and liothyronine could be produced on a large scale from protected L-3,5-dinitrotyrosine by inserting the iodine substituents after formation of the ether bond [99]. This synthesis also led to the production of D-T_4 and D-T_3. However, optically pure preparations could not be obtained easily.

A method adapted from the biological synthesis was used for some time to produce levothyroxine. Two molecules of L-diiodotyrosine are coupled at pH 9.5 in the presence of manganese dioxide at 60 °C. Levothyroxine is produced with a yield of 2.8 %. The reaction of diiodotyrosine with 4-hydroxy-3,5-diiodo-phenylpyruvic acid proceeds similarly except that yields up to 50 % can be obtained [100, 101].

A total synthesis of T_4 and T_3 was developed by Hoechst in 1963 and involves racemate resolution at the level of diiodothyronine [102, 103]. The reaction steps are shown below:

Most other methods in the large-scale production of thyroid hormones are modifications of the procedure described by HILLMANN in 1956 [104, 105]. The ether bond in thyronine is synthesized by using diaryliodonium salts and the only slightly reactive diiodotyrosine (see top of next page) [106, 107].

L-Thyronine is made from L-tyrosine, obtained by protein hydrolysis (e.g., of wool). A number of methods are available for obtaining T_3 and T_4 by subsequent iodination [102, 104, 108]. The arylation of diiodotyrosine with iodonium salts permits the recovery of optically pure levo- and dextrothyroxine preparations. Especially in the case of dextrothyroxine, which is used therapeutically to lower cholesterol levels, the amount of L-isomer should not exceed 0.2 % [109]. Chemically pure T_4 and T_3 preparations are obtained by preparative column chromatography [110]. Analogues of the thyroid hormones and ^{14}C-labeled preparations are also produced by the above methods [111–113].

Analysis and Testing. The following methods are used to test the identity and purity of iodoamino acids: iodine determination; UV absorption [114]; paper [115], thin-layer [116], and gas chromatography [117], polarography [118]; enzymatic analysis [109]; and radioimmunoassays (→Diagnostic Reagents, Chap. 2.5.→Diagnostic Reagents, Chap. 2.6.→Diagnostic Reagents, Chap. 3.2.).

Producers of thyroid hormones in Germany and Austria are Henning (Berlin), Hoechst (Frankfurt), and Sanabo (Vienna).

Trade names are listed in Table 1, see right.

Table 1. Selected trade names of thyroid hormone preparations

Trade name	Producer	Country
Sodium levothyroxine		
Eferox	Efeka	FRG
Eltroxin	Glaxo	Denmark, Great Britain, Switzerland
Euthyrox	Merck	Austria, Belgium, FRG
L-Thyroxin Henning	Henning Berlin	FRG
L-Thyroxine Roche	Roche	France
Levoroxine	Bariatric	USA
Levothroid	USV	USA
Levothyrox	Merck-Clevenot	France
Levothyroxine Sodium	Armour-Yamanouchi	Japan
Synthroid	Flint	USA
Thevier	Glaxo	FRG
Thyrex	Sanabo	Austria
Sodium liothyronine		
Cynomel	Uhlmann-Eyrand	Switzerland
Cynomel	Merrell	France
Tertroxin	Glaxo	Denmark, Great Britain
Thybon	Hoechst	FRG
Combination preparations of sodium levothyroxine and sodium liothyronine		
Novothyral	Merck	FRG
Prothyrid	Henning Berlin	FRG
Thyroxin-T_3	Henning Berlin	FRG
Combination preparation of sodium levothyroxine and iodine		
Jodthyrox	Merck	FRG
Injection solutions (sodium levothyroxine)		
L-Thyroxin inject Henning	Henning Berlin	FRG
Synthroid	Flint	USA
Injection solutions (sodium liothyronine)		
Tertroxin	Glaxo	Denmark
Thyrotardin inject	Henning Berlin	FRG

2.2. Hormones of the Adrenal Medulla

The hormones of the adrenal medulla are the catecholamines *adrenaline* (epinephrine) and *noradrenaline* (norepinephrine). The catecholamines act on α and β-adrenoreceptors in the central nervous system, in the autonomous nervous system, and in other tissues (Figure see right) [119].

They also modify the metabolism of many cells [120]. Both hormones are synthesized in the adrenal medulla. After transsection of the human adrenal gland, the central adrenal medulla is clearly visible because it is darker than the surrounding adrenal cortex. The adrenal medulla and the adrenal cortex are regulated by different mechanisms, the adrenal cortex being under hormonal control, whereas the adrenal medulla is under nervous control. The blood-pressure increasing effect of an adrenal extract was described in 1985 by OLIVER and SCHÄFER [121]. The first chemical synthesis of adrenaline was performed in 1904 by STOLZ, the definitive elucidation of its structure by FRIEDMANN was in 1906.

Normally only noradrenaline is secreted; the medulla secretion of adrenaline is restricted to acute stressful situations which require brief, maximal activation of cadiovascular function, and enhanced central nervous tone. Noradrenaline administered intravenously or subcutaneously has a predominantly peripheral action on blood pressure and cardiovascular function. After subcutaneous injection, absorption is much delayed due to potent vasoconstriction. The adrenal medulla also produces *dopamine*, a precursor of noradrenaline.

Dopamine

Low concentrations of dopamine have therapeutic effects on specific dopamine receptors in the kidney, increasing the glomerular filtration rate in shock syndromes [122]. At increasing concentrations, dopamine stimulates α-adrenoreceptors, it is therefore administered by infusion at a controlled rate to avoid undesirable vasoconstriction. A lack of dopamine is also responsible for Parkinson's disease (→Parkinsonism Treatment).

The catecholamines have major endogenous functions as synaptic transmitters in the central regulation of blood pressure [122]. Noradrenaline stored in synaptic vesicles is released from the presynaptic nerve endings and acts on receptors in the postsynaptic membrane. Its local concentration in the synapse is controlled by reuptake mechanisms. Noradrenaline also acts as a neurotransmitter in the autonomous nervous system.

Noradrenaline [*51-41-2*], levarterenol, norepinephrine, R (−)- or D (−)-2-amino-1- (3,4-dihydroxyphenyl)ethanol; $C_8H_{11}NO_3$, M_r 169.2, *mp* 217 – 218 °C (decomp.), sparingly soluble in water and ethanol;

Hydrochloride: $C_8H_{11}NO_3 \cdot HCl$, M_r 205.6, *mp* 145 – 146 °C, readily soluble in water, α_D^{25} − 40° (6 % aqueous solution);

Hydrogen tartrate: $C_8H_{11}NO_3 \cdot C_4H_6O_6$, M_r 319.3, *mp* 158 – 159 °C, α_D^{25} − 10.7° (1.6 % aqueous solution).

Adrenaline [*329-65-7*], suprarenin, epinephrine, R (−)- or D (−)-1- (3,4-dihydroxyphenyl)-2-methylaminoethanol $C_9H_{13}NO_3$, M_r 183.2, *mp* 211 – 212 °C, α_D^{25} − 50 – 53° (5 % in 0.5 mol/L HCl);

Hydrogen tartrate: $C_9H_{13}NO_3 \cdot C_4H_6O_6$, M_r 333.3, *mp* 149 – 152 °C, α_D^{25} − 14.5°

Hydrochloride: $C_9H_{13}NO_3 \cdot HCl$, M_r 219.7, *mp* 206 °C.

The levorotatory isomers of both noradrenaline and adrenaline are 15 – 40 times more potent in several test systems. This is also a general characteristic of many other catecholamines.

Synthesis. Both compounds are obtained from 4-chloroacetylcatechol which is prepared from catechol by reaction with chloroacetic acid and $POCl_3$.

For the preparation of adrenaline, 4-chloroacetylcatechol is reacted with methylamine, the keto group is converted to the hydroxy group by catalytic hydration and the racemic adrenaline base thus obtained is cleaved with tartaric acid. For noradrenaline, the 4-chloroacetylcatechol is reacted with ammonia.

Therapeutic Uses. Adrenaline and noradrenaline have limited therapeutic importance,

because their duration of action is short and therapy of hypotension would require administration by infusion. Their rapid rate of disappearance after presynaptic release is a physiological prerequisite for rapid synaptic transmission. However, it has promoted the development of numerous synthetic catecholamine derivatives and indirect sympathomimetics [123] that act on the stored neurotransmitters in synaptic vesicles (→Antihypotensives; →Sympatholytics and Sympathomimetics).

Many catecholamine derivatives and sympathomimetic compounds have been developed in an attempt to obtain specific stimulation of α-adrenoreceptors and β(2)-adrenoreceptors involved in smooth muscle relaxation, e.g. as bronchodilatory compounds [123]. Research on nonselective β-adrenoreceptor blockers and selective β-blocking agents has been very successful [124] (see also → β-Receptor Blocking Agents). The indirect sympathomimetics displace catecholamines from their storage vesicles and thus temporarily enhance postsynaptic stimulation [125]. This effect is abolished if the storage vesicles are first depleted of catecholamines by administration of reserpine [126].

Clinical Uses. Adrenaline has important clinical applications in internal medicine, surgery, and dental medicine. It provides rapid relief in hypersensitivity reactions caused by anaphylactic and allergic reactions (by injection or infusion), in cardiogenic shock caused by myocardial infarction, and relieves respiratory distress due to bronchospasm when administered by oral inhalation. In surgery and dental medicine, adrenaline is used as a hemostatic agent; it is administered by infiltration or locally application on bleeding surfaces. In combination with local anesthetics it prolongs an anesthesia by preventing diffusion of the anesthetic from the site of injection. Adrenaline acts as a bronchodilatory and antiallergic compound, because it prevents the release of histamine and other mediators of inflammation [126]. Noradrenaline and related synthetic sympathomimetic amines that act predominantly on α-adrenoreceptors have similar clinical uses to adrenaline.

3. Steroid Sex Hormones (→ Steroids)

3.1. Introduction

The sex hormones, like the hormones of the adrenal cortex, are steroids with the following general formula:

All substituents below the plane of the ring system are designated as α and those above the plane of the molecule as β. These orientations can be indicated with a dashed or solid line, respectively. The substituent R may be an alkyl residue or an oxygen function (for further details on steroid structures, see [127, 128]). These compounds are called "steroids" because they bear a great structural resemblance to the naturally occurring sterols [127]. The sex hormones are classified as

1) *androgens* (male sex hormones, e.g., testosterone);
2) *estrogens* (female sex hormones, e.g., estrone, estradiol, estriol); and
3) *gestagens* (female sex hormones, e.g., progesterone).

Naturally occurring steroids have several asymmetric carbon atoms (centers of chirality) and are optically active. They are defined as belonging to the "normal series" [127, 128]. Synthetic steroids are considered to belong to the normal series when C-10 or, if this position is not asymmetric (as in the estrogens), C-13 has the same configuration as in cholesterol. If all the centers of asymmetry in the steroid molecule have the opposite configuration to normal (i.e., mirror image of the normal form), the compound carries the prefix "ent" (enantiomer). A racemate is an equimolar mixture of the normal and the enantiomeric forms of a steroid molecule and is indicated by the prefix "rac" [128].

Of the large number of possible stereoisomers of sex hormones, only the isomer with the normal (natural) configuration is active (in this respect, estrogen is the simplest sex hormone;

it has four centers of asymmetry, 16 stereoisomers, and 8 racemates). All other stereoisomers either are less active, are inactive, or exert other effects. Cholesterol is the principal mammalian sterol and is biosynthesized from 18 molecules of acetyl coenzyme A (acetyl-CoA) by a complex route involving consecutive formation of mevalonic acid, farnesyl pyrophosphate, squalene, lanosterol, and cholesterol. For further details, see [133, pp. 20 – 70].

Cholesterol is the biochemical precursor of both the sexual and the adrenal steroid hormones. Figure 4 briefly summarizes the most important steps of cholesterol transformation, as well as the principal enzymes involved.

Commercial methods used in the production of sex hormones or their precursors can be divided into four groups:

1) *Partial chemical synthesis* of steroid hormones from natural materials, that have the

Figure 4. Biosynthesis of steroid sex hormones [130, 133]
Enzymes: a) 3β-Hydroxy-Δ^5-steroid dehydrogenase; b) Steroid-Δ-isomerase; c) Steroid-17α-monooxygenase; d) C-17,20-Lyase; e) 17β-Hydroxysteroid dehydrogenase; f) Aromatase; g) 5α-Reductase

steroid nucleus (e.g., sterols, saposterols), was the first method used for commercial production of sex hormones; it still has considerable economic importance.

2) *Microbiological degradation* of sterols, such as cholesterol, stigmasterol, ergosterol, and β-sitosterol, which cannot otherwise be efficiently converted into steroid intermediates, has rapidly become commercially important [141–144].
3) The *total synthesis* of steroid hormones involves synthesizing the sterically complex steroid skeleton from inexpensive starting substances. This method is only important for steroids that do not occur in nature (see Section 3.4) [134–136].
4) The *extraction* of sex hormones or their conjugates from organic tissue or urine is the oldest method for isolating therapeutically important sex hormones. However, it is also the most unproductive because the hormones occur in very low concentration (10 mg of estrone can be isolated from 1 L of mare urine and 1 mg of progesterone from 35 g of pig corpus luteum). Today, this method is only used to recover a mixture of estrogen conjugates from the urine of pregnant mares, which is required for the menopause preparation Presomen. However, hormone extraction is still a very important analytical tool, e.g., in the identification and isolation of metabolites of sex hormones [132].

3.2. Partial Chemical Synthesis of Steroid Intermediates

3.2.1. Raw Materials

Raw materials for the partial chemical synthesis of steroid intermediates must fulfill the following requirements:

1) they must contain the steroid nucleus,
2) they must belong to the normal series,
3) they must occur in nature in sufficient quantities, and
4) they must be easily convertible into sex hormones by simple chemical reactions.

The most important raw materials are listed in Table 2 [146]. All have a hydroxyl group at position 3 and a double bond between C-5 and C-6. These common structural elements readily permit the introduction of an unsaturated keto group in ring A (e.g., by Oppenauer oxidation). These four compounds differ from each other with respect to the side chain at C-17; cholesterol and β-sitosterol possess a saturated side chain that is not easily accessible to chemical attack and subsequent modification. Stigmasterol has a double bond in its side chain and is thus more susceptible to chemical modification. Diosgenin contains a spiroketal side chain which not only makes it easy to modify, but also permits insertion of a double bond between C-16 and C-17.

Table 2. Starting substances for the partial synthesis of steroid intermediates

Name and natural source	Formula
Diosgenin [*512-04-9*] (**1**): Dioscoreaceae	 **1**
Stigmasterol [*83-48-7*] (**2**): soybean oil	 **2**
β-Sitosterol [*83-46-5*] (**3**): wheat germ oil, soybean oil, sugarcane wax	 **3**
Cholesterol [*57-88-5*] (**4**): wool grease, spinal cord, brain	 **4**

The steroid starting materials and their derivatives obtained by chemical or microbiological modification are shown in Figures 5 and

Figure 5. Steroid starting materials and their chemically synthesized derivatives

6, respectively. The derivatives, in turn, are starting materials for the synthesis of different series of sex hormones (see Table 3). Almost all steroid hormones belonging to the pregnane, (21 carbon atoms in the steroid skeleton), androstane (19 carbon atoms), and estrane (18 carbon atoms) series can be obtained by chemical modification of diosgenin (**1**) and stigmasterol (**2**). Microbiological modification of cholesterol (**4**), β-sitosterol (**3**), and stigmasterol (**2**) and subsequent chemical conversions have only yielded androstanes and estranes [141–144].

Table 3. Steroid derivatives for the synthesis of steroid hormones

Steroid derivative	Hormone product
Dehydropregnenolone (**5**), progesterone (**7**)	1) Gestagens of the 17α-hydroxyprogesterone series 2) Adrenal cortex hormones (corticoids)
Adrostenolone (**8**)	1) Androgens 2) Gestagens of the 17α-ethynyltestosterone series 3) Anabolic androstane steroids

Figure 6. Steroid starting materials and their microbiologically synthesized derivatives

Cholesterol [*57-88-5*], $C_{27}H_{46}O$, M_r 386.6, *mp* 148 °C (for structure see Table 2), was an important starting material in the early industrial production of sex hormones. Oxidation of cholesterol or its 5,6-dibromide derivative with chromic acid gave androstenolone acetate [127]; maximum yields were 7 – 8 %. Today, both cholesterol and β-sitosterol have little importance as starting materials for chemical syntheses. However, they are all more important as raw materials for syntheses involving microbiological degradation of the side chain (see Section 3.3) [141–144].

Cholesterol occurs in animal tissue at the following concentrations, in weight percent:

Skeletal muscle	0.09 – 0.12
Liver	0.32 – 0.61
Brain (calf)	2.11 – 2.36
Kidney	0.28
Egg yolk	2 – 3.9

Spinal cord (calf)	4
Wool fat	15

It can be recovered from these sources by extraction with chlorinated hydrocarbons, if necessary, after saponification of cholesterol esters. Purification is difficult because cholesterol is often isolated with lanosterol and other triterpenes [145].

Stigmasterol [*83-48-7*], $C_{29}H_{48}O$, M_r 412.7, *mp* 170 °C, and **β-sitosterol** [*83-46-5*], $C_{29}H_{50}O$, M_r 414.7, *mp* 140 °C (for structures see Table 2), are two additional steroid starting materials. After diosgenin, stigmasterol is the most important raw material for steroid hormone synthesis. As a result of the double bond between C-22 and C-23 in the side chain, chemical modification of stigmasterol yields either pregnenolone [145], via bisnorcholic acid, or progesterone [127], via bisnorcholic aldehyde. Both compounds are key substances in the production of pregnane, androstane, and estrane hormones. Microbiological degradation of stigmasterol and β-sitosterol yields androstadienedione (see Fig. 6).

Stigmasterol occurs with β-sitosterol at a concentration of 12 – 25 % in the nonsaponifiable fraction of soybean oil. The sterols are extracted as a mixture, but their similarity makes the purification and isolation of stigmasterol extremely difficult. Thus, stigmasterol is not a starting material for chemical syntheses. However, microbiological degradation can be carried out conveniently with this sterol mixture.

Diosgenin [*512-04-9*], $C_{27}H_{42}O_3$, M_r414.6, *mp* 208 °C (for structure see Table 2), is a steroid sapogenin. When compared with the sterols mentioned above, diosgenin is the most suitable candidate as a starting material for the production of steroids and sex hormones [127]. Not until the discovery of this compound and the elaboration of a commercially feasible method for degradation of the spiroketal side chain, to give dehydropregnenolone (**5**) (see Fig. 5), was the large-scale industrial production of sex hormones possible. Almost all steroid hormones, including those of the adrenal cortex, can be derived from dehydropregnenolone (see Fig. 5). Since the early 1950s diosgenin has become the most important steroid raw material. Its discovery gave a tremendous technological boost to the production of sex hormones. The price of progesterone dropped within three years from $ 80 to $ 3 per gram, and sufficient amounts of sex hormones became available for medical use.

Diosgenin occurs as a 3-glycoside (dioscin) [*19057-60-4*] in numerous *Liliaceae* and *Dioscoreaceae* species and is extracted from the air-dried rhizomes of *D. mexicana, D. floribunda,* and *D. composita* (also called barbasco) with ethanol [127, 145]. The extracts are concentrated by evaporation, glycoside cleavage is achieved by heating with dilute hydrochloric or sulfuric acid, and crude diosgenin is isolated by filtration. This raw material can be purified by crystallization from alcohol; however, it is usually employed without previous purification in the production of dehydropregnenolone (see Section 3.2.2).

3.2.2. Partial Synthesis

This section describes only the synthesis of intermediates having special importance for the commercial production of sex hormones used as active ingredients in drugs.

Batch synthesis of the active substances is still prevalent; however, both automation by programmed monitoring and semicontinuous or continuous methods are becoming increasingly important.

Synthesis of 3β-Acetoxydehydropregnenolone. 3β-Acetoxydehydropregnenolone [*979-02-2*], also called dehydropregnenolone acetate(**5b**), is synthesized from diosgenin [127, 145] by a method first developed by Marker and coworkers and later improved upon by several teams. Diosgenin acetate is heated to 190 – 200 °C with acetic anhydride or a homologous compound and is converted to pseudodiosgenin diacetate which, in turn, on mild oxidation with chromic acid in glacial acetic acid yields the ketone diosone. Hydrolysis with dilute alkali gives dehydropregnenolone or its acetate (**5b**), depending on reaction conditions, with an overall yield of ca. 45 % (see first figure on next page).

Dehydropregnenolone is the key substance in the synthesis of all the steroid and sex hormones derived from diosgenin (see Fig. 5).

Progesterone (**7**)

Synthesis of Progesterone. The natural gestagen progesterone [*57-83-0*] (**7**) is used as an active ingredient in gestagen preparations (see Section 3.7.2), and is also an important intermediate in the production of adrenal cortical hormones. Two methods are available for the preparation of progesterone:

Selective hydrogenation of dehydropregnenolone acetate (**5b**) with palladium charcoal results in the retention of the Δ^5 double bond and the formation of pregnenolone acetate (**6b**). This compound is saponified and then oxidized (Oppenauer) in benzene or toluene to progesterone [127, 145] by refluxing with cyclohexanone and aluminum isopropylate. Yields of ca. 85 % are obtained.

The *conversion of stigmasterol* (**2**) to progesterone can be carried out in several ways. The Ciba method uses 5,6-dibromostigmasterol (**11**) as the starting compound [148] (see lower figure in left column).

Oxidation of the dibromide with chromic acid followed by zinc reduction gives bisnorcholic acid (**12**), which is then converted to the methyl ketone (**13**). The 5,6-double bond of compound **13** is protected by bromination before the compound is oxidized with peracid to give the 20-acetate derivative (**14**). In the final step, saponification, Oppenauer oxidation, and oxidation with chromic acid give progesterone with a total yield of 40 % (based on **12**).

In a method developed at Upjohn [127], the hydroxyl group of stigmasterol (**2**) is first oxidized (Oppenauer) to the ketone. If this ketone is ozonized under specific conditions, only the double bond in the side chain is attacked, yielding the aldehyde (**15**). Compound (**15**) is con-

verted first to the enamine (**16**) by azeotropic distillation with piperidine and, finally, to progesterone (**7**) by oxidation. The overall yield is 60 %.

Synthesis of 3β-Acetoxy-5-androsten-17-one. 3β-Acetoxy-5-androsten-17-one [*53-43-0*] (**8**) (formerly known as androstenolone) and its acetate (**8b**) serve as starting materials for the synthesis of testosterone, estrone, and other androgens and estrogens including 19-norandrostane steroids derived from nortestosterone. Two of the most important production methods are described below.

1) 3β-Acetoxy-5,16-pregnadien-20-one (**5**) (16-dehydropregnenolone acetate), derived from diosgenin (**1**), is heated with hydroxylamine hydrochloride and sodium acetate or pyridine in ethanol to give the oxime (**17**) [149]. Beckmann rearrangement of **17** yields the enamide (**18**), which is then subjected to mild acid hydrolysis to give androstenolone acetate (**8b**).

2) The second method uses pregnenolone acetate (**6b**), synthesized as described in page 28, as the starting material. Compound **6b** is first converted to the oxime and then subjected to a Beckmann rearrangement to give the acetamide (**19**), which in turn undergoes alkaline hydrolysis to yield the corresponding amine [150]. Reaction of the amine with hypochloric acid gives the chloramine (**20**), which is then treated with alkoxide (ketimine), followed by acetylation and acid hydrolysis to produce androstenolone acetate [151].

Synthesis of Estrone. Estrone [*53-16-7*] (**10**) is an active ingredient of commercial hormone preparations; it is also an important starting substance in the production of estradiol, ethinyl estradiol, other estrogenic steroid hormones, and 19-norandrostane compounds.

Estrone is synthesized from androstenolone (**8**), which is first hydrogenated with palladium charcoal to give epiandrosterone (**21**). Subsequent oxidation with chromic acid yields the 3,17-diketone, which is then treated with bromine in acetic acid to give the 2,4-dibromide. The dibromide, in turn, is converted to androstadienedione (**9**) by elimination of two molecules of hydrogen bromide. Dissolution of **9** in tetralin or mineral oil and pyrolysis (i.e., brief exposure to high temperature, ca. 600 °C) in the presence of quartz beads yields estrone (**10**, see next page) [152].

The "aromatization" of androstadienedione to give estrone has long been the subject of intensive research [127, 145]. Chemical synthesis of compound **9** from compound **8** requires four steps, whereas microbiological synthesis proceeds directly [153].

Synthesis of Testosterone. Testosterone [*58-22-0*] (**23**) is used therapeutically as the free steroid or as an ester. Testosterone is synthesized from androstenolone acetate (**8b**)

which is reduced to the 17β-alcohol with Raney nickel and then esterified with benzoyl chloride in pyridine. This protecting ester group permits partial saponification of the 3-acetate with methanolic sodium hydroxide solution to yield the 3-hydroxy compound (**22**). Subsequent Oppenauer oxidation produces the testosterone benzoate (**23**), which is then subjected to alkaline hydrolysis to give testosterone (**23**) [145]. Testosterone 17-esters can be obtained by normal esterification procedures.

Synthesis of 19-Nortestosterone. 19-Nortestosterone [*434-22-0*] (**26**), which differs from testosterone (**23**) in that it does not have a methyl group at position 19, is the parent compound of the anabolic 19-norandrostane steroids and of the highly gestagenic hormones belonging to the norethisterone series.

Birch reduction of the methyl ether of estrone (**24**) is one of the most important methods used for the partial synthesis of 19-norandrostane compounds [154, 155].

The methyl ether is obtained by methylation of estrone with dimethyl sulfate and methanolic potassium hydroxide solution and then reduced to the alcohol with a complex hydride (e.g., $LiAlH_4$ or $NaBH_4$). The aromatic ring is subsequently reduced with lithium in liquid ammonia and diethyl ether in the presence of a small amount of ethanol to give the enolether (**25**). Treatment with methanolic hydrochloric acid yields 19-nortestosterone (**26**).

Synthesis of Norethisterone [127, 145, 156]. 17α-Ethynyl compounds may be obtained by ethynylation of 17-keto steroids. Most of these ethynyl compounds not only have interesting biological properties but also have a high oral activity. Norethisterone [*68-22-4*] (**29**) is a highly potent, orally active gestagen; many of its derivatives have characteristic activities.

An exceptionally short synthesis starts with the enolether (**25**) prepared by Birch reduction of estrone methyl ether (**24**). Oppenauer oxidation [157] of **25** yields the 17-keto compound, which can be ethynylated to compound **28** by one of the usual methods [156]. Subsequent acid hydrolysis gives norethisterone.

Another method used in the production of 19-norsteroids entails the functionalization and subsequent elimination of the 19-methyl group of 19-methyl steroids to produce the corresponding 19-nor compounds [158]. Both the aromatization of ring A and the subsequent Birch reduction are circumvented. Thus, androstenolone acetate (**8b**) can be converted to norethisterone (**29**), and pregnenolone acetate (**6b**) to gestonorone caproate (**66**, see below) [178].

The synthesis of norethisterone (**29**) and norethynodrel (**71**) proceeds as follows. Addition of hypochloric acid to androstenolone acetate (**8b**) gives the corresponding chlorohydrin. On reaction with lead tetraacetate and iodine, the chlorohydrin is converted to a cyclic ether, which in turn is saponified and oxidized to give a diketone. Reductive opening of the cyclic ether ring with zinc in glacial acetic acid produces a 19-hydroxy derivative, and subsequent oxidation with chromic acid gives the 10β-carboxylic acid, which is decarboxylated to the diketone by heating with pyridine. Partial ketalization yields the acetal, and ethynylation with sodium acetylide followed by treatment with either a weak acid (malonic acid) or a mineral acid finally yields norethynodrel (**71**) or norethisterone (**29**), respectively.

Synthesis of 17-Acetoxyprogesterone. Introduction of an acetoxy group at position 17 of progesterone (**7**) considerably increases the oral activity of this gestagen. 17-Acetoxyprogesterone [*302-23-8*] (**32**) is the active ingredient of a large number of commercial gestagen preparations and the parent compound of many gestagens with excellent oral activity [127, 145].

One of the syntheses available for the preparation of 17-acetoxyprogesterone starts with dehydropregnenolone acetate (**5b**), obtained from diosgenin. Compound **5b** is first converted to the 16α,17-epoxide and then to the bromohydrin (**30**). Subsequent debromination gives

the 3-formate (**31**), which is subjected to acid-catalyzed acetylation and Oppenauer oxidation to give compound **32**.

3.3. Microbiological Methods for the Synthesis of Steroid Intermediates

Since the beginning of the 1950s, microbiological conversion has become increasingly important in the commercial production of steroid hormones. Advantages of this technique include stereospecific reactions at positions that are not accessible to chemical reaction, mild reaction conditions, and reaction coupling (e.g., dehydrogenation and isomerization). These advantages more than compensate for the disadvantages (low substrate concentrations and, therefore, large reaction volumes; higher personnel and energy costs; more sophisticated equipment; and sterility of all media and materials involved in the reaction).

Microbiological reduction has become the key reaction in the total synthesis of sex hormones. This is the only economic way to produce pure enantiomers of the natural, optically active form of these hormones and to circumvent

Figure 7. Schematic of a fermentation plant [159]

the tedious and inefficient resolution of racemates (see Section 3.4).

Microbiological degradation can be used to convert naturally occurring sterols, such as cholesterol, β-sitosterol, stigmasterol, and ergosterol, to androstadienedione (**9**). Chemical degradation of these abundantly occurring compounds is inefficient and unprofitable. The technology used in the microbiological conversion of steroids is similar to that used in the production of antibiotics (→Antibiotics, Chap. 5.4.). The required quantity of the desired microorganisms is obtained by growing the cells in one or two prefermentation steps. Then, reaction with the relevant substrate occurs in the main fermenter. All steps must be carried out under sterile conditions to avoid contamination. The flow diagram of a fermentation plant is shown in Figure 7. The main fermenter can have a volume up to 50 000 L [159].

Degradation to Androstadienedione. The complete fermentative degradation of sterols to carbon dioxide and water by microbial enzymes has been known for a long time. Methods have been developed to prevent complete breakdown of the sterol nucleus after degradation of the side chain, e.g., at the stage of androstadienedione (**9**) [141, 142, 144]. In all these methods, inexpensive sterols (cholesterol, sitosterol, stigmasterol, and ergosterol) serve as starting materials, a variety of microorganisms are used, and the aerobic fermentation must be carried out in the presence of inhibitors of the enzymes that continue degradation to carbon dioxide and water (e.g., inorganic heavy-metal salts, such as nickel sulfate, and organic chelating agents). An overview of the microbiological degradation methods available and their yields of androstadienedione is presented in Table 4.

3.4. Total Synthesis of Sex Hormones

The consumption of sex hormones as oral contraceptive agents as well as the demand for steroids to produce adrenal cortical hormones has increased dramatically since 1960 so that demands could not be met by available raw material sources [147]. For this reason, the total synthesis of steroid substances is very important. In addition, total synthesis of steroids permits the production of structural elements that are impossible or extremely difficult to obtain with partial syntheses (e.g., production of homologous 13-alkyl steroids).

Synthesis of d-Norgestrel. D-Norgestrel [*6533-00-2*] (**38**), the gestagenic component of the contraceptives Neogynon and Stedirild, is produced by total synthesis [159–161]. 6-Methoxy-1-tetralone is converted to the vinyl alcohol (**33**) with vinylmagnesium chloride. Condensation of **33** with 2-ethylcyclopentane-1,3-dione gives the secodione (**34**). Stereospecific

Table 4. Microbiological degradation used for the synthesis of androstadienedione

Sterol used as starting material	Microorganism	Inhibitor	Yield of androstadienedione, %	Reference
Cholesterol (**4**)	*Mycobacterium phlei*	8-hydroxyquinoline	38	[144]
		nickel(II) sulfate	50	[141]
	Nocardia	cobalt(II) chloride	13	[142]
	Arthrobacter	nickel(II) sulfate	25	
β-Sitosterol (**3**)	*Mycobacterium phlei*	8-hydroxyquinoline	18	[144]
	Arthrobacter	nickel(II) sulfate	13	[142]
Stigmasterol (**2**)	*Mycobacterium phlei*		27	[144]

microbiological reduction of **34** yields the β-hydroxy ketone (**35**), which has two asymmetric carbon atoms (C-13 and C-17). Compound **35** is optically active and belongs to the normal series; i.e., C-13 and C-17 have the same configuration as in natural steroid compounds. Because subsequent reactions are stereospecific, the final product (D-norgestrel) retains the optical activity and normal configuration introduced by microbiological reduction [161] (see figure on previous page).

Acidic cyclization of **35** produces **36**, which has a double bond between C-14 and C-15. In the subsequent Birch reduction, the $\Delta^{8,9}$ double bond and the aromatic ring are reduced. Oppenauer oxidation of the 17β-hydroxyl group of the resulting dienolether leads to the corresponding ketone. Subsequent ethynylation of the ketone and cleavage of the enolether yield D-norgestrel (**38**).

Synthesis of Norgestrienone. Norgestrienone [*848-21-5*] (**46**) is the gestagenic component of the oral contraceptive Planor, registered only in France [162]. Michael addition of methyl 5-oxo-6-heptenoate to 2-methylcyclopentane-1,3-dione produces the methyl ester of the triketocarboxylic acid (**39**). As in the synthesis of D-norgestrel, **39** is then subjected to partial, stereospecific reduction with the help of microorganisms. The resulting optically active β-hydroxy ketone (**40**) belongs to the normal series [163]. Again, subsequent reactions proceed stereospecifically, and the final product retains the correct steric configuration attained in one of the early steps.

Compound **40** is converted to the formate (**41**) by aldol condensation, acid-catalyzed hydrolysis, and formylation. Compound **41** is converted to the saturated acetate (**42**) by stereoselective hydrogenation, saponification, and acetylation. Treatment with acetic anhydride gives the enol lactone (**43**). Subsequent Grignard reaction yields **44**, which already possesses rings B, C, and D of the steroid skeleton. Compound **44** is benzoylated at position 17 and then converted to compound **45** by aldol condensation and enamine formation with pyrrolidine. Subsequent dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, protection of the resulting 3-keto group by oxime formation, oxidation to the 17-ketone, ethynylation, and oxime cleavage finally yield norgestrienone (**46**) [163].

Both syntheses use inexpensive chemicals as starting materials and apply microbiological reduction (production of an asymmetric carbon atom) to skillfully circumvent the formation of racemates and their inefficient resolution. Older versions of both methods produced racemates. Consequently, the contraceptives Eugynon (Schering) and Stediril (Wyeth) contain racemic norgestrel as gestagen.

3.5. Estrogens

3.5.1. General Aspects

Physiology and Clinical Applications. The first sex hormone to be isolated was estrone (**10**). It was recovered from the urine of pregnant humans by Doisy and Butenandt in 1929; later, the urine of pregnant mares was used as a richer source of estrogens. The structure was elucidated in 1932 by Butenandt, Marrian, and Haslewood.

The naturally occurring estrogens estradiol (**47**), estrone (**10**), and estriol (**48**), together with the gestagen, progesterone (**7**), regulate the menstrual cycle in humans and several animal species [164]. In addition, estrogenic hormones influence the growth and blood circulation of the uterus, vagina, and mammary glands. They are used in substitution therapy to control estrogen deficiency caused by ovarian hypofunction, castration, or menopause. They are also used in suppression therapy to suppress gonadotropin-induced ovulation and the endogenous production of estrogens [164]. Because of the latter, estrogens are used together with gestagens as combination contraceptive agents (→Contraception, Chap. 4.). A defined dose ratio of estrogen to gestagen together with a set mode of administration prevents ovulation and, consequently, fertilization with minimal side effects. The hormones are also administered in osteoporosis senilis, prostate carcinoma, mastocarcinoma, and for suppression of lactation [164].

Lists of the most important commercially available estrogenic sex hormones are given in Tables 5 (natural estrogens) and 6 (estradiol derivatives). They are available as single substances or as combination preparations.

Bioassays. Four types of bioassay are used for the quantitative determination of estrogenic hormones:

1) *Vaginal Smear Test.* The vaginal smear test, developed by Allen and Doisy [130, 131], is specific for active estrogens and permits the isolation of estrogenic sex hormones. Subcutaneous or oral administration of these hormones leads to a marked proliferation of the vaginal epithelium and keratinization of the surface cell layers (Schollen stage) in small rodents. These characteristic changes in cell structure are visible on microscopic examination of vaginal smears. When equal hormone doses are used, the degree of change depends on the duration of the effect and the potency of the estrogenic substances. The reference substances used are estradiol (**47**) for subcutaneous application, ethinyl estradiol (**51**) for oral application, and estradiol heptanoate or undecenoate for long-acting substances with depot activity. Castrated animals are used to avoid the effects of the natural sexual cycle.
2) *Sialic Acid Content of Mouse Vagina.* Administration of estrogen to castrated mice leads to a dose-dependent reduction of the sialic acid content of the vagina [165]. After subcutaneous or oral treatment, the animals are sacrificed, the vaginas are removed and processed, and the sialic acid content is determined colorimetrically. This test is specific for estrogenic substances; the sialic acid content is a measure of the potency of the estrogen. Reference substances are estradiol for subcutaneous application and ethinyl estradiol for oral administration.
3) *Vaginal Opening Test.* The vagina of rodents remains closed until sexual maturity. Active estrogens cause premature opening of the vagina. This test, however, is not estrogen-specific because androgens and anabolic substances produce a similar effect.
4) *Uterine Growth Test.* Administration of estrogens to rodents causes increased growth of the endometrium and myometrium of the uterus. The increase in uterine weight is proportional to the dose and potency of the estrogen administered.

3.5.2. Natural Estrogens and Estradiol Derivatives

Natural Estrogens. The naturally occurring estrogens, estrone (**10**), estradiol (**47**), and estriol (**48**), as well as the estrogens from mare urine, equilin (**49**), equilenin (**50**), and their 17-dihydro compounds, are of considerable importance in the treatment of menopausal symptoms (for structures, see Table 5) [161]. However, very high oral doses are required to elicit responses because these compounds are rapidly metabolized and inactivated in the liver. Injection preparations for parenteral administration can only be produced in the form of crystal suspensions because of the low solubility.

Estradiol Esters. Esterification of naturally occurring estrogens with longer chain carboxylic acids is an important method for increasing their duration of action. In contrast with free estrogens, oily solutions of esterified estrogens can be produced for depot injection preparations.

17-Alkylated Estradiol Derivatives. Alkylation of estradiol derivatives at position 17 increases their oral activity many times. The 17-alkyl group imparts stability to biodegradation which, in natural estrogens, begins with oxidation of the secondary 17-hydroxyl group to a ketone [131, 133]. As a result of the high oral activity of these estrogenic compounds,

Table 6. Estradiol derivatives

* [166].

[e.g., ethinyl estradiol (**51**) and its methyl ether, mestranol (**52**)], they are used widely in combination preparations for oral contraception (→Contraception, Chap. 4.1.).

3.5.3. Nonsteroidal Estrogens

Estrogenic activity is not restricted to the estrogenic sex hormones. Certain plant constituents,

bituminous components of the Seefeld oil shale, easily synthesized stilbene derivatives, and their dihydro compounds have estrogenic properties [130]. The therapeutic application of stilbestrol derivatives in clinical medicine is limited. They are of greater importance in veterinary medicine (e.g., in the artificial caponizing of chickens).

The parent compounds of the nonsteroidal estrogens are diethylstilbestrol [*56-53-1*] (**53**), hexestrol [*84-16-2*] (**54**), and dienestrol [*84-17-3*] (**55**).

Diethylstilbestrol (**53**)

Hexestrol (**54**)

Dienestrol (**55**)

Compounds **53**–**55** are used in the free form, as their diethers or diesters, or with substituted aromatic rings or double bonds. The most important commercial preparations are listed in Table 7.

3.5.4. Antiestrogens [130, 131]

The term antiestrogen designates a very heterogeneous group of substances that counteract the effects of estrogen. The use of antiestrogens is indicated primarily in the palliative treatment of metastasizing mastocarcinoma. In addition, they can be used to treat benign prostate hyperplasia and endometriosis.

Antiestrogens can be divided into three groups on the basis of their mode of action:

1) *Competitive Antagonists.* These active antiestrogenic substances act by binding competitively to the estradiol receptor. The nonsteroidal stilbene derivatives tamoxifen [*10540-29-1*], cyclofenil [*2624-43-3*], and clomiphene [*911-45-5*] have practical importance. Chemical modification of estradiol has also produced derivatives with antiestrogenic properties. However, these compounds usually exert a mixture of dosage-dependent, antagonistic and agonistic effects (see upper figure in next column).
2) *Aromatase Inhibitors.* Transformation of androstenedione to estrone is catalyzed by the enzyme aromatase (see Fig. 4). A series of steroidal and nonsteroidal substances reversibly or irreversibly inhibit this enzyme system and are thus suitable agents for lowering the biological level of estrogen. In addition to androstane derivatives, imidazole

Table 7. Stilbestrol derivatives

R*	Generic name	CAS registry no.	Trade name (manufacturer)

Atamestan [*96301-34-7*]
(Schering)

CGS 16949 A
[*102676-47-1*]
(Ciba-Geigy)

3) *Antigonadotropic Substances.* Another way of reducing ovarian estrogen production is by inhibiting hypophyseal gonadotropin secretion. Although Danazol [*17230-88-5*] has a weak androgenic, anabolic component, it primarily exhibits a central gonadotropin-inhibiting effect. Danazol is especially useful for the treatment of endometriosis.

Danazol [*17230-88-5*]
(Sterling Winthrop)

3.6. Androgens and Anabolic Agents [140]

3.6.1. General Aspects

Physiology and Clinical Applications. Testosterone (**23**), the principal male sex hormone (androgen), was isolated in 1935 from bull testes (100 kg of bull testis gave approximately 10 mg of testosterone), and its structure was subsequently elucidated. A weaker androgenic substance androsterone (**56**) was isolated in 1931 from human urine and shown to be a breakdown product of testosterone.

Androsterone (**56**)

Testosterone synthesis occurs in the testis and is regulated by the hypophyseal luteinizing hormone (LH). However, small amounts of androgens are also produced in the ovaries, the adrenal glands, and the placenta. The chief functions of testosterone are to ensure normal development of the seminal vesicles, prostate, epididymis, and Cowper glands and to maintain secondary male characteristics (facial hair, deep voice). Spermatogenesis, on the other hand, is regulated by the follicle-stimulating hormone (FSH).

Clinical use of androgens is indicated in cases of androgen deficiency, such as climacterium virile, hypogenitalism, prostate hypertrophy, and other potency disorders (substitution therapy). The administration of testosterone also has a suppressive effect on the hypophysis; it inhibits the release of LH and FSH and, consequently, spermatogenesis. A "rebound effect" is observed after treatment stops; i.e., the production of LH and spermatogenesis are intensified. This effect may be desirable in cases of oligozoospermia. Androgens are prescribed for carcinoma of the breast, carcinoma of the uterus, or endometriosis, as well as to inhibit lactation.

Testosterone and androsterone, like all androgens, exert an anabolic influence and stimulate protein synthesis in muscle and bone. They

are used therapeutically in the treatment of consumptive disease, anorexia, old-age infirmity, osteoporosis, etc. Chemical modification of androgens has produced substances with a high anabolic-to-androgenic potency, which can also be administered to women. However, all anabolic agents do have a certain residual androgenic effect [167].

Bioassays. Two types of bioassay are used for the quantitative determination of androgens and anabolic agents:

Assay of Androgenic and Anabolic Activity [168]. The function and size of the accessory sex glands (seminal vesicles and prostate) and of the musculus levator ani (a muscle of the perineal complex) in castrated male rats depend on the presence of androgens. The fresh weights of the seminal vesicles (androgenic activity) and levator ani (anabolic effect) are measured. The anabolic and androgenic effects are then determined from a dose – response curve. The organ weights are compared with values given by reference substances (testosterone propionate for subcutaneous application and 17α-methyltesterone for oral application). The relative potencies are expressed as fractions or multiples of the activity of the reference substance.

Chicken Comb Test. The comb of a young cockerel grows on administration of androgens. After standard treatment, the comb and body weights are measured, and the ratio thus obtained is compared with that produced by reference substances. Again, testosterone propionate is used as reference for subcutaneous application and 17α-methyltestosterone for oral administration.

3.6.2. Androgens

Testosterone and Testosterone Esters. A large number of preparations contain testosterone (**23**) in the free form or as one of its esters; examples are listed in Table 8. The rapid breakdown of testosterone (oxidation at position 17, reduction at position 3, and reduction of the double bond) and its subsequent inactivation can be slowed down by esterification with longer chain fatty acids; consequently, the duration of its action can be effectively prolonged (depot effect).

Other Androgens. Commercial preparations available for androgen therapy are listed in Table 9. They are androgens with good oral activity, sufficient duration of action, and a low inhibitory effect on spermatogenesis [140]. Intro-

duction of a methyl group at positions 17 and 1 of the steroid nucleus, a hydroxymethyl group at C-2, and the production of 9α-fluoro-11β-hydroxy compounds have proved particularly interesting. However, 17-methyl derivatives tax the liver to a greater extent and are contraindicated in cases of liver malfunction.

3.6.3. Antiandrogens [139, 140]

The term antiandrogen designates any substance that inhibits the action of the male sex hormone testosterone. Examples are cyproterone acetate [*427-51-0*] (for synthesis, see [181]) and flutamide [*13311-84-7*], which represent different classes of substances.

Cyproterone acetate

Flutamide

Both antiandrogens function by competitively displacing testosterone from the androgen receptor. Whereas flutamide has no other endocrinal side effects, cyproterone acetate possesses a strong gestagenic activity and, consequently, can also be used in combination preparations as an oral contraceptive. Antiandrogens

are applied primarily in the treatment of prostate tumors, hypersexuality in men, pubertas praecox in young men, androgen-dependent acne, seborrhea, and alopecia in women.

Biological Testing of Antiandrogenic Activity. Administration of an antiandrogen to pregnant rodents at the fetal sexual differentiation stage produces an androgen deficit; consequently, normal development of the exterior sex characteristics of the male fetus does not occur. A mixture of male and female characteristics is obtained, depending on the potency of the administered antiandrogen .

3.6.4. Anabolic Agents [167]

In many cases, chemical modification of the steroid nucleus of androgens of the 19-norandrostane, androstane, and androstanolone series increases their anabolic effects at the expense of their androgenic activity. Generally, the production of long-chain esters prolongs the action of subcutaneous preparations (depot effect) and methylation at C-17 increases oral potency.

19-Norandrostane Compounds. 19-Nortestosterone (**26**) is the parent compound of the series of therapeutically important anabolic agents listed in Table 10. Apart from esterification with long-chain acids, the introduction of

Table 11. Anabolic testosterone derivatives

an 18-methyl group or a 4-hydroxyl group, the reduction or removal of the 3-keto group, and alkylation at C-17 give rise to potent anabolic agents.

Testosterone Compounds. Some anabolic testosterone derivatives are listed in Table 11. Introduction of a hydroxyl group or a chlorine atom at position 4, methylation at C-7, introduction of a thioacetyl group or an additional double bond between C-1 and C-2 favorably influence activity, and 17-methylation produces high oral potency.

Androstanolone Compounds. Androstanolone (**57**) is the parent compound of another series of anabolic sex hormones [175]; see Table 12. The remaining androgenic activity of androstanolone is further reduced by methylation at C-1 or C-2, or by replacing C-2 with oxygen or the A ring with a heterocyclic ring. Again, methylation at C-17 increases oral activity, but also increases stress on the liver.

3.7. Gestagens

3.7.1. General Aspects

Physiology and Clinical Applications. Progesterone (**7**) is the most important representative of a group of female sex hormones known as gestagens. Ludwig Frenkel discovered progesterone in 1903, but not until 1934 was progesterone isolated and its structure analyzed.

Progesterone acts with another group of female sex hormones, the estrogens (see Section 3.5), to regulate the sexual cycle. After ovulation, progesterone is continuously formed by

the corpus luteum and prepares the endometrium of the uterus for implantation of the fertilized egg (transition from proliferation to secretion) [130, 131]. It prevents renewed ovulation and fertilization during pregnancy, decreases the tonus of the uterus, and thus maintains pregnancy. The inhibition of ovulation is the basis for the use of gestagens as contraceptive agents. The administration of gestagens "imitates" pregnancy–the secretion of FSH by the hypophysis diminishes, thus preventing maturation and release of the ovum [176]. The most important application of gestagens, alone or in combination with estrogens, is in the inhibition of ovulation or contraception (suppression therapy). In addition, gestagens are important in the treatment of deficiency symptoms such as imminent abortion, sterility, and irregularities of the menstrual cycle (substitution therapy). The strong inhibition of gonadotropin secretion exerted by some gestagens is also exploited in the treatment of prostate adenoma.

Hormonal Contraception [130, 131]. Hormonal contraception is based on the suppression of ovulation in the middle of the menstrual cycle. The secretion of LH, which is reponsible for ovulation, does not occur under the influence of a gestagen – estrogen combination preparation. An additional contraceptive effect is achieved by the fact that inhibitors of ovulation also influence the development of the endometrium and the consistency of the cervical secretion. The hormonal contraceptives presently available contain different types of gestagenic components

and varying doses of individual components. Although older combination preparations had a high proportional estrogen, the tendency is to reduce estrogen content because this is primarily responsible for side effects. The successful search for new gestagens has produced a generation of low-dosage ovulation inhibitors. New administration regimes (sequential preparations, two- and three-phase preparations) have resulted in further dose reduction; the doses of estrogen and gestagen are adapted to the course of the menstrual cycle (see also →Contraception, Chap. 4. [130, 131].

Bioassays. Two types of bioassay are used for the quantitative determinations of gestagens:

Clauberg Test [130]. The synergistic action of estrogens and gestagens induces characteristic changes of the endometrium. The endometrium proliferates under the action of estrogens and undergoes characteristic morphological changes under the subsequent influence of active gestagens. These changes are most apparent in rabbits; they are evaluated histologically and compared with those produced by reference substances. This test is used routinely in the search for novel gestagenic sex hormones and also permits determination of relative potencies.

Maintenance of Pregnancy. In pregnant rodents, removal of the corpus luteum or ovaries results in the termination of pregnancy. Active gestagens can maintain pregnancy in castrated, pregnant animals. The test is performed on pregnant rats and is used for qualitative characterization of the activity spectrum of a compound. However, it is not suitable for the determination of relative potencies.

3.7.2. Gestagens of the Pregnane and 19-Norpregnane Series

Progesterone (**7**), the naturally occurring gestagen, is administered subcutaneously as an injection solution; very high oral doses are required to elicit responses because of rapid degradation in the liver. For this reason, progesterone is not used as an oral contraceptive.

The extensive search for gestagens with high oral activity and low side effects started with three compounds that were more orally active than progesterone [127]: hydroxyprogesterone acetate (**58**), ethisterone (**68**), and 19-norethisterone (**29**), with approximately 30, 20, and 100 times the potency of progesterone, respectively. Modification of hydroxyprogesterone acetate (**58**), in particular substitution at C-6 and C-17, produced a large number of highly active oral gestagens. Some of these preparations and their trade names are listed in Table 13 (see next pages). Characteristic modifications include introduction of the Δ^6 double bond (**61**–**65**), substitution at C-6 with chlorine or a methyl group (**60**–**62**, **64**), changing the ring A – B coupling (**65**), and transition to the 19-nor series (**66**). The gestagens listed in Table 13 differ in their effectiveness; those that exert a strong antiovulatory effect (central inhibition) are of considerable importance as contraceptives (**60**–**62**, **67**). Other gestagens exert a stronger proliferative effect on the endometrium [176]. Gestonorone caproate (**66**) is also used in the treatment of prostate adenoma.

3.7.3. Gestagens of the Androstane Series

Insertion of a 17α-ethynyl group into testosterone yields ethisterone (**68**) which, surprisingly, is only slightly androgenic but is a highly potent oral gestagen [127]. The synthesis of ethisterone was the first successful step in the search for orally active gestagens. Dimethisterone (**69**) is even more potent than ethisterone; these are the only two products of this series on the market (Table 14, see next pages).

3.7.4. Gestagens of the 19-Norandrostane Series

Compounds of the 19-norandrostane (or estrone) series can be prepared easily by Birch reduction of estrone methyl ether. Examples commercially available as contraceptive agents are listed in Table 15 (see next pages) [176]. Transition from the androstane to the 19-norandrostane series further increases the biological potency of a large number of these sex hormones. 19-Norethisterone (**29**) was synthesized as an analogue of ethisterone (**68**); like ethisterone, it has only slight androgenic activity, but it is a fivefold stronger oral gestagen. A number of very

[a] [130], [b] [131], [c] [162], [d] [163], [e] [160], [f] [161], [g] [158], [h] [180], [i] [182], [j] [183], [k] [184].

potent oral gestagens with strong antiovulatory activity has been derived from 19-norethisterone by methods such as acetylation (**70**, **72**, **74**), isomerization of the double bond (**71**), reduction (**72**), elimination of the 3-keto group (**73**), or enolether formation (**74**) [130, 131]. The totally synthetic gestagens–norgestrienone (**46**), norgestrel (**38**, racemate) and D-norgestrel (**38**), desogestrel (**75**), gestoden (**76**), and norgestimat (**77**)–all belong to this series.

3.7.5. Antigestagens [185]

Antigestagens may be either progesterone antagonists or inhibitors of progesterone synthesis.

Competitive progesterone antagonists are substances that inhibit gestagen function by blocking the progesterone receptor. The first compound found to have this property was mifepristone [*84371-65-3*] Roussel-Uclaf [RU 486, 11β- (4-dimethylaminophenyl)-17β-hydroxy-17α-(1-propynyl)estra-4,9-dien-3-one]. This substance can be administered in fertility control (nidation inhibition, menstruation commencement, abortion induction), obstetrics, and the treatment of hormone-dependent tumors.

Mifepristone (Roussel-Uclaf)

Inhibitors of progesterone synthesis block the action of progesterone by preventing its formation [139]. At present, attempts are being made to inhibit the conversion of pregnenolone to progesterone by reversibly or irreversibly blocking the enzyme Δ^5-3β-hydroxysteroid dehydrogenase. Epostane [*80471-63-2*] (4α,5α-epoxy-17β-hydroxy-4β,17α-dimethyl-3-oxo-androstane-2α-carbonitrile) is being tested clinically [186]. Some nonsteroidal compounds (e.g., aminogluthetimide and antimycotics of the ketoconazole family) can also suppress steroid biosynthesis by enzyme inhibition.

Epostane (Sterling-Winthrop)

4. Adrenal Steroid Hormones

(→ Steroids)

4.1. Introduction

Very few classes of substances exert so many physiologically and therapeutically useful effects as the steroid hormones of the adrenal cortex. These hormones, also called corticosteroids or corticoids, are divided into two groups depending on their physiological mode of action: the *glucocorticoids* promote glycogen formation from carbohydrates and gluconeogenesis from proteins, whereas the *mineralocorticoids* act primarily on electrolyte and water metabolism. The corticoids are thus responsible for the maintenance of important metabolic functions and are essential for life. The life of adrenalectomized animals is maintained by continuous corticoid administration (survival test) [191]. The "liver glycogen test" was developed especially for glucocorticoids [187].

Administration of glucocorticoids results in glycogen accumulation in the liver of normal or adrenalectomized, fed or fasting animals. The liver glycogen test measures the glycogen content of liver homogenate after the treated animals have been sacrificed.

The simultaneous increase of blood glucose and certain gluconeogenetic enzymes in the liver is a further useful parameter for determining the glucocorticoid potency of a test compound.

Both groups of substances are C_{21} steroids and are structurally related to the pregnane series.

Pregnane skeleton

The important structural characteristics of these compounds are the α,β-unsaturated 3-keto-$\Delta^{4(5)}$ system and an α-hydroxyketone group in the 17β side chain. An 11β-hydroxyl group or 11-keto group is important for a predominantly glucocorticoid effect. In the mineralocorticoids, this group is absent (cortexone) or physiologically inactivated (e.g., lactol formation as in aldosterone). An additional hydroxyl group at the 17α-position increases glucocorticoid activity significantly.

Approximately 50 steroids of the pregnane (steroids with 21 carbon atoms), androstane (19 carbon atoms), and estrane series (18 carbon atoms) have been obtained from the adrenal cortex since the 1930s. These steroids have all been isolated and their structures analyzed, but only seven compounds are considered to be typical corticosteroids:

Glucocorticoids

1) Cortisol (**78**), also called hydrocortisone, 17α-hydroxycorticosterone, $11\beta,17\alpha$,21-trihydroxypregn-4-ene-3,20-dione
2) Cortisone, 17α,21-dihydroxypregn-4-ene-3,11,20-trione
3) Corticosterone, 11β,21-dihydroxypregn-4-ene-3,20-dione
4) 11-Dehydrocorticosterone, 21-hydroxypregn-4-ene-3,11,20-trione

Mineralocorticoids

1) Cortexone, deoxycorticosterone, 21-hydroxypregn-4-ene-3,20-dione
2) Cortexolone, 17α-hydroxydeoxycorticosterone, 17α,21-dihydroxypregn-4-ene-3,20-dione
3) Aldosterone (**79**), 18,21-dihydroxy-11β,18-oxidopregn-4-ene-3,20-dione

Cortisol (**78**)

Aldosterone (**79**)

Of the steroids listed above, only cortisol, corticosterone, and aldosterone exhibit hormonal characteristics. The other corticoids, despite their often high physiological activity, are considered precursors or metabolites of the true adrenal cortical hormones.

4.2. Historical Aspects

The isolation and structural analyses of naturally occurring corticoids were carried out by Wintersteiner, Pfiffner, Kendall, and Reichstein. Crystalline aldosterone was first obtained in 1953 from adrenal cortical tissue by Reichstein and coworkers, who then proceeded to elucidate the structure and configuration of this steroid. The mineralocorticoid cortexone (commercially available since 1938) was the first corticoid to be used in the treatment of Addison's disease, a corticosteroid deficiency caused by damage or destruction of the adrenal glands. Cortexone can be synthesized easily. At first, cortisone and cortisol were employed primarily in the treatment of rheumatic disease, but after the mid-1950s, cortisone, cortisol, and especially the newly developed, chemically modified glucocorticoids achieved tremendous therapeutic and industrial importance.

The former industrial extraction of naturally occurring corticoids, especially cortisone and cortisol, from animal adrenal glands [196] is no longer important. It has been completely replaced by partially synthetic production methods.

4.3. Physiology and Mode of Action

The adrenal cortex is a peripheral endocrine gland whose hormone production (with the exception of aldosterone) is regulated by the anterior pituitary hormone, adrenocorticotropic hormone (ACTH). The formation of aldosterone is independent of ACTH; it is controlled primarily by the angiotensin – renin system and by the functional coupling of adrenal cortex, hypophysis, and hypothalamus.

The adrenal corticosteroid hormones play an important part in the metabolism of carbohydrates, proteins, and minerals. Their importance is exemplified by the fact that even slight stress to the organism causes a rapid increase in the activity of the adrenal cortex.

The adrenal steroid hormones cannot be strictly divided into mineralocorticoids and glucocorticoids because they all produce the effects of both groups. Thus, aldosterone exerts its prime action as a mineralocorticoid but also

has some glucocorticoid activity; for example, in the liver glycogen test [191], it is only slightly less potent than cortisone.

The *mineralocorticoids* are responsible for maintaining the correct distribution of sodium and potassium between the cell contents and the extracellular fluid and, consequently, for the maintenance of osmotic equilibrium. Malfunction of the adrenal cortex results in increased or diminished excretion of sodium and chlorine, with correspondingly diminished or increased excretion of potassium. Severe disturbances in water metabolism occur. Aldosterone exerts a much stronger effect on mineral metabolism than the other hormones. It has approximately 25 – 30 times the sodium-retaining activity and 5 times the potassium excretory activity of deoxycorticosterone. In humans, ca. 100 – 200 µg of aldosterone is synthesized daily.

In the case of natural or chemically modified *glucocorticoids,* a distinction must be made between their physiological action and their subsequently discovered therapeutically important pharmacodynamic effects. The primary physiological functions of glucocorticoids are to increase glycogen formation in the liver, raise the blood sugar level, and augment gluconeogenesis from amino acids by protein breakdown (catabolic effect). Moreover, glucocorticoids enable the organism to withstand stress (e.g., physical or psychological demands) and to maintain a normal internal state (homeostasis). In humans, 15 – 40 mg of cortisol is produced daily, but ten times this amount can be secreted under stress conditions. The amount of corticosterone synthesized daily is 1.3 – 4 mg.

Androgenic hormones, such as 11-hydroxyandrostenedione and androsterone, and to a small extent estrogenic hormones are also produced in the adrenal cortex [194].

4.4. Therapeutic Uses of Glucocorticoids

The therapeutic effects of glucocorticoids, particularly of chemically modified corticoids, are based primarily on the inhibition of proliferative reactions of mesenchymal tissue, especially allergic and inflammatory tissue reactions (e.g., polyarthritis, pleuritis). However, glucocorticoids are used to treat the symptoms but not the cause of these diseases. Glucocorticoids reduce the number of lymphocytes and eosinophilic granulocytes in the blood. Because their main effects are anti-inflammatory, antiexudative, cytotoxic, immunosuppressive, antitoxic, and antipruretic, they may be applied in the treatment of the following syndromes:

Substitution Therapy. Glucocorticoids can be used in acute and chronic adrenal cortical insufficiency, adrenogenital syndrome, thyroidal crises, Addison's disease (in combination with mineralocorticoids), and inhibition therapy of hyperadrenal cortical states.

Pharmacodynamic Therapy. The most important indications for glucocorticoid treatment are acute and chronic polyarthritis; rheumatic fever; allergic reactions such as asthma and obstructive bronchitis (→ Antiasthmatic Agents, Chap. 3.); cardiogenic, anaphylactic, and traumatic shock; stress situations; collagen disease; autoimmune disease; shock caused by burns and acid burns; poisoning; acute attack of gout; malignant tumors (especially leukemia and lymphogranulomatosis); and local application in a number of skin afflictions and dermatoses (especially eczema and exanthema, → Dermatotherapeutic Agents). In bacterial diseases, glucocorticoids can be administered with antibiotics or chemotherapeutic agents.

4.5. Therapy and Side Effects

Types of Therapy. Three types of corticoid therapy are possible: systemic, topical, and local. *Systemic therapy* can in turn be divided into oral application (administration of corticoids in the free 21-alcohol form or in the ester form as tablets, capsules, dragées, etc.); intravenous application (administration as a water-soluble 21-ester, e.g., 21-sodium hemisuccinate, 21-disodium phosphate, or 21-dialkylamino carboxylate); and intramuscular application (administration of corticoids as a free 21-alcohol or a short- or long-chain 21-ester). In *topical corticoid therapy,* free 21-alcohols or their esters are injected as crystal suspensions into a joint or tissue cavity.

Local corticoid therapy is used commonly to treat skin disease. Corticoids are again applied as the free 21-alcohols or as specially structured 21- or 17-esters in ointments, creams, lotions, or sprays. A broad-spectrum antibiotic is usually

added to local corticoid preparations to prevent bacterial infection (e.g., 0.5 % neomycin sulfate or 0.1 % gentamicin).

Side Effects. Medium- or long-term systemic application of glucocorticoids can cause the following side effects: hypercorticism or Cushing's syndrome (adiposity of the trunk, moon-shaped face, steroid diabetes, hypertension); tumor formation in the gastrointestinal tract; retardation of granulation and scar formation; osteoporosis; hypophyseal inhibition; atrophy of the adrenal cortex; psychological effects (e.g., euphoria); increased risk of infection; endocrine disturbance; morphological changes of the skeletal muscle and muscular atrophy; or adynamia and fatigue.

The central mineralocorticoid side effects of cortisone and cortisol have been eliminated to a large extent by the development of chemically modified glucocorticoids. To reduce the risk of side effects in systemic anti-inflammatory therapy, glucocorticoids are often combined with nonsteroidal anti-inflammatory agents (→ Analgesics and Antipyretics, Chap. 3.).

Dosage. The dose equivalence is used to compare the effects of systemically administered glucocorticoids; it is the glucocorticoid or anti-inflammatory activity relative to that produced by cortisol (cortisol equivalence = 1). The average maintenance dose in milligrams per day is also important in establishing the dosage. Both values are listed in Table 16 for the most important glucocorticoids used systemically in medicine today; the Cushing threshold dosage is also given.

4.6. Biosynthesis and Metabolism

Biosynthesis of the adrenal corticosteroid hormones starts with the conversion of cholesterol to pregnenolone, which is subsequently oxidized to progesterone (see Fig. 4). This compound is then converted to the glucocorticoids by primary hydroxylation at C-17 and subsequent hydroxylation at C-21 (cortisone) and C-11 (cortisol). In contrast, biosynthesis of the mineralocorticoids is initiated by primary hydroxylation at C-21. The C-17 hydroxylase is unable to attack the C-21 hydroxylated product. Glucocorticoids are produced in the central zona fasciculata and the mineralocorticoids in the outer zona glomerulosa of the adrenal cortex.

Corticoid metabolism occurs primarily in the liver, the major enzymatic degradation reactions being [190]

1) hydrogenation of the double bonds at the 4,5-positions and, in the case of $\Delta^{1,4}$ corticoids, the 1,2-positions to give products with a saturated ring A;
2) reduction of the 3-keto, 20-keto and, in the case of 11-oxocorticoids, 11-keto groups to the corresponding hydroxyl groups; and
3) oxidative cleavage of the side chains at the 17β-position to give 17-keto steroids.

The metabolites of adrenal cortical steroids are excreted in the urine as 3-glucuronides or 3-sulfates, e.g., as glucuronides of type **80** (tetrahydrocortisol derivatives) or type **81** (tetrahydroandrostane derivatives).

Table 16. Cortisol equivalence, average maintenance dose, and Cushing threshold dose of the most important glucocorticoids used in systemic human therapy listed in order of increasing effectiveness [193, 197]

Glucocorticoid	Cortisol equivalence (cortisol = 1)	Average maintenance dose, mg/d	Cushing thresholddose, mg/d
Cortisone	0.8	10 – 50	50
Cortisol	1.0	10 – 50	40
Prednylidene	2	12 – 15	18 – 24
Prednison, prednisolone	4	5 – 15	10
Fluocortolone	4	2.5 – 12.5	10 – 15
6α-Methylprednisolone	5	6 – 10	8
Triamcinolone	5 – 10	6 – 8	8
Paramethasone	10	2 – 6	4 – 6
Fludrocortisone	15		
Dexamethasone	20 – 25	1 – 2	2
Betamethasone	25 – 50	1 – 1.5	2

80

81

4.7. Detection Methods

The special detection methods used in the analysis of corticoids are almost all based on chemical reactions specific for the side chain at position 17. Important reactions are degradation with periodic acid and chromic acid [187], and oxidation of the C-17 side chain with sodium bismuthate to give the 17-keto derivative (e.g., androsterone) or 17-ethio acid (17β-carboxylic acid) [198]. Another method for identification of the dihydroxyacetone side chain is the Porter–Silber reaction [199], which is based on the formation of a yellow dye on heating with phenylhydrazine and sulfuric acid. This substance has a characteristic UV absorption band at 410 nm, and its molar extinction can be measured easily. For further details on chemical, spectral, and radioactive detection methods for corticoids, see [194].

4.8. Naturally Occurring Glucocorticoids

4.8.1. Properties and Uses

Cortisone [*53-06-5*] (**82**), $C_{21}H_{28}O_5$, M_r 360.46, *mp* 220–224 °C, $[\alpha]_D^{20}$ +209° (95 % ethanol), and **cortisol** [*50-23-7*] (**78**),

Cortisone (**82**)

$C_{21}H_{30}O_5$, M_r 362.47, *mp* 217–220 °C, $[\alpha]_D^{20}$ +167° (ethanol), are glucocorticoid hormones whose importance has diminished considerably because of their relatively low potency and, above all, their pronounced side effects (especially the strong mineralocorticoid action). They have been replaced by chemically modified corticoids and are used only in exceptional cases, namely, in substitution therapy and in special preparations for local application (e.g., in ear, nose, and throat conditions and in ophthalmology). However, cortisone and cortisol are even more important today as intermediates in the synthesis of chemically modified corticoids. Because totally synthetic methods are not economically feasible, the industrial production of cortisone and cortisol is still based on a series of efficient, partially synthetic methods. These methods use inexpensive, simple plant steroids as raw materials.

Total synthesis of cortisone was achieved in 1951 by Woodward and coworkers [200] and a year later by Sarett and coworkers [201]. A total synthesis of cortisone had already been published in 1950 by Wendler and coworkers [202]. These methods are solely of scientific interest and have no industrial importance. Although the large-scale corticoid total syntheses developed by Roussel–Uclaf have been improved considerably, they are still not as economical as the partially synthetic processes [203–205].

Trade Names. Despite their minor therapeutic importance, a large number of cortisone and cortisol preparations are still available on the market. Only a few typical representatives can be listed here: Cortisone: Cortisone "Ciba" (Ciba, Wehr, FRG); Scheroson (Schering).

Cortisol: Scheroson F (Schering); Ficortril (Pfizer, FRG); Hydrocort (Ferring, FRG); Hydrocortisone "Hoechst" (Hoechst).

Corticosterone [*50-22-6*], $C_{21}H_{30}O_4$, M_r 346.45, *mp* 180–182 °C, $[\alpha]_D^{25}$ +223° (alcohol), and **11-dehydrocorticosterone** [*72-23-1*],

Corticosterone, X = HO, H
11-Dehydrocorticosterone, X = O

$C_{21}H_{28}O_4$, M_r 344.43, *mp* 178–180 °C, $[\alpha]_D^{25}$ +258 ° (alcohol), are two other glucocor-

ticoids. They do not have a hydroxyl group at position 17; therefore, they can be considered as 17-deoxycortisol and 17-deoxycortisone, respectively. In comparison with cortisol and cortisone, these compounds have a lower glucocorticoid activity but exert a stronger mineralocorticoid effect. For this reason, these corticoids have achieved neither industrial nor therapeutic importance. For partial synthesis, see [189].

4.8.2. Partial Synthesis of Cortisone [191]

The most important methods for the industrial production of cortisone (**82**) from steroid raw materials are

1) production from progesterone,
2) production from 16-dehydropregnenolone via cortexolone, and
3) production from bile acid.

The first two methods are more important because they use an elegant microbiological process to insert the oxygen function at C-11.

Production from Progesterone. Production of cortisone from progesterone was developed in 1952 and is important because progesterone can be produced cheaply from diosgenin (see Section 3.2.2). Progesterone is converted to 11α-hydroxyprogesterone (**83**) by a high-yield (90 %) microbiological oxidation with the mold *Rhizopus arrhizus* or *R. nigricans* [206, 207]. The method used by Upjohn proceeds as shown in Figure 8 [208]. 11α-hydroxyprogesterone (**83**) is oxidized with chromium trioxide to 11-oxoprogesterone, which in turn is converted to the sodium salt of 21-(ethoxalyl)-11-oxoprogesterone (**84**) with diethyl oxalate and sodium ethoxide [209]. The next step involves treatment with 2 molar equivalents of bromine. The resulting 21-dibromo derivative is not further isolated but is subjected to a Favorskii rearrangement in the presence of sodium methoxide, to yield compound **85**. The 3-oxo-Δ^4 group of this compound is protected by formation of the enamine (**86**). Reduction of compound **86** with lithium aluminum hydride leads to the formation of compound **87**, in which both the 21-carbomethoxy and the 11-keto groups are reduced to alcohol groups. After hydrolytic cleavage of the enamine group

Figure 8. Synthesis of cortisone from 11α-hydroxyprogesterone

and esterification of the 21-hydroxyl group with acetic anhydride – pyridine, compound **88** is obtained (the 11β-hydroxyl group is not esterified for steric reasons). Compound **88** is subjected to chromic acid oxidation and then ef-

fectively converted to cortisone acetate (**90**), by using a method developed at Upjohn, with *N*-methylmorpholine *N*-oxide and osmium tetroxide [210]. The total yield is 20 – 25 %, based on 11α-hydroxyprogesterone (**83**).

Production from 16-Dehydropregnenolone. 16-Dehydropregnenolone (**92**) is prepared easily on a large scale from diosgenin (see Section 3.2.2). A method developed by JULIAN [211] and modified by Syntex [212] requires several steps to convert this compound to cortexolone (Fig. 9; **98**).

16-Dehydropregnenolone (**92**), obtained by hydrolysis of 16-dehydropregnenolone acetate, is converted with alkaline hydrogen peroxide to 16α,17α-oxidopregnenolone (**93**), which in turn reacts with hydrobromic acid to give the bromohydrin (**94**). After removal of the 16β-bromine atom by hydrogenation with palladium – hydrogen and partial esterification of the 3-hydroxyl group with formic acid, 3β-formoxy-17α-hydroxypregnene (**95**) is formed. This compound can also be prepared by using the method described in [213]. Compound **95** is converted to the tribromo derivative (**96**) with 2 molar equivalents of bromine; then the Δ^5 double bond is regenerated with sodium iodide, and the 21-bromine group is replaced by the 21-acetoxy group with potassium acetate. Esterification of the 17α-hydroxyl group with acetic anhydride and toluene-*p*-sulfonic acid gives the diester (**97**). Direct Oppenauer oxidation (during which the 3-formoxy group near the less vulnerable acetate groups at C-17 and C-21 is partially saponified) and subsequent alkaline saponification of the 17- and 21-acetate groups yield cortexolone (**98**). The total yield of **98** based on **95** is 45 – 50 %. Again, the hydroxyl group at C-11 is introduced microbiologically. Compound **98** is reacted with the fungus *Cunninghamella blakesleeana* or *Curvularia lunata* to yield up to 77 % cortisol and 22 % cortisone [214, 215]. Microbiological hydroxylation with *Absisia glauca* converts compound **98** to a mixture of equal parts cortisol (**78**) and 11α-cortisol (**99**), the 11α-epimer of cortisol, with a total yield of 90 % [216, 217]. Compound **99** is separated from cortisol by means of its acetate and then oxidized to cortisone (**82**). Another Upjohn method permits the specific hydroxylation of compound **98** to 11α-cortisol **99** and gives a yield of ca. 85 %. 11α-Cortisol can subsequently be oxidized to cortisone with chromium trioxide [218, 219].

Figure 9. Synthesis of cortisone from 16-dehydropregnenolone

Production from Bile Acid. Cortisone was first produced from bile acid by SARETT [220] and by KENDALL of the Merck Corporation [221]. Bile acid (i.e., cholic acid [*81-25-4*], **100**) is isolated from the bile of slaughtered animals and has a hydroxyl group at position 12. Although the synthesis of cortisone from cholic acid originally entailed 36 reaction steps, compared with the considerably shorter syntheses from progesterone and 16-dehydropregnenolone, it is still used today.

Cholic acid (**100**)

A large number of improvements and changes have been made (reviewed in [188]), and recommendation of any one variation is difficult (cf. [187–189, 191, 195]). However, all variations share the following basic concepts:

1) Elimination of the 7α-hydroxyl group of cholic acid to give 7-deoxycholic acid [209]
2) Transfer of the hydroxyl function at position 12 of deoxycholic acid to position 11
3) Partial degradation of the side chain at C-17 of the bile acid and conversion to the 17-dihydroxyacetone side chain characteristic of corticoids
4) Introduction of the 3-keto-4,5-dehydro structure into the corticoid molecule

Ergosterol (**101**)

Hecogenin (**102**)

Miscellaneous Methods. Other commercial methods of cortisone production start with ergosterol (**101**) and stigmasterol [222], phytosterols of yeast and soybean oil, or with the sapogenin hecogenin (**102**), obtained as a waste product in the recovery of sisal [223, 224] (see left figure below). However, these methods no longer have any importance.

4.8.3. Partial Synthesis of Cortisol

Pregnane derivatives are generally used as starting materials in the partially synthetic commercial production of cortisol. These derivatives already have an 11-keto or 11α-hydroxyl group and are obtained in the production of cortisone from progesterone and 16-dehydropregnenolone described in Section 4.8.2. The Upjohn process (Fig. 8) allows conversion of 11α-hydroxyprogesterone (**83**), obtained microbiologically from progesterone, to cortisol [196, 225].

In the American Cyanamide method, cortisol (**78**) is produced from 11α-cortisol (**99**) or cortisone (**82**) with a yield of 72 % [196, 226]. Reaction with ethylene glycol and subsequent oxidation with chromium trioxide yield the 3,20-bisketal (**103**).

103

Treatment with sodium borohydride stereospecifically reduces the 11-keto group to an 11β-hydroxyl group, which is finally hydrolyzed to cortisol (**78**).

Another cortisol production process, developed by Upjohn [227], starts with pregnane-3α,17α-diol-11,20-dione (**104**) obtained from progesterone [228]. Here, the 3α-hydroxyl group is oxidized to a 3-keto group with *tert*-butyl hypochlorite with simultaneous chlorine substitution at position 4. The bisketal (**105**) is subsequently obtained by reaction with ethylene

glycol. Conversion of the bisketal to cortisol requires six additional steps and proceeds with a yield of 15 % [196].

104 **105**

Other commercially important biochemical methods are available in which cortexolone (**98**) can be stereoselectively hydroxylated at the 11β-position to give cortisol (**78**) with yields of approximately 40 %. This is achieved microbiologically by using *Cunninghamella blakesleeana* [229] or *Curvularia lunata* [230] (see also Fig. 9 and [231]).

The production of cortisol (**78**) from cortisone acetate (**90**) [232] involves formation of the 3,20-bissemicarbazone. The 11-keto function does not react with semicarbazide for steric reasons. Subsequently, the 11-keto group is reduced with potassium borohydride, whereby the 11-hydroxyl group formed acquires the desired β-configuration and the 21-acetate group is simultaneously hydrolyzed. Cortisol is finally obtained by hydrolytic cleavage of the semicarbazone group with nitric acid.

4.9. Naturally Occurring Mineralocorticoids and Antagonists

The most important mineralocorticoids are deoxycorticosterone (**112**), also called *cortexone,* and the more powerful, physiologically more important *aldosterone* [*52-39-1*] (**79**). *Spironolactone* (**115**) is an important synthetic aldosterone antagonist. In comparison with the glucocorticoids, the mineralocorticoids are seldom used as therapeutic agents because specific mineralocorticoid activity is required in only a few conditions, e.g., in the treatment of Addison's disease, a rare condition that requires substitution therapy, and (with glucocorticoids) in stress situations. Cortexone is commercially important as an intermediate or starting material in the synthesis of other steroids.

Although a number of interesting studies have been carried out on the synthesis of aldosterone (**79**), it has little importance as a therapeutic agent and intermediate. Aldosterone has 20 – 30 times the mineralocorticoid potency of cortexone 21-acetate and one-third the glucocorticoid activity of cortisone, whereas cortexone acetate has no significant glucocorticoid activity.

Both mineralocorticoids are administered systemically. Cortexone is generally given parenterally as an oily solution of a 21-ester (e.g., acetate, cyclopentylpropionate, trimethylacetate, or heptanoate). Substitution therapy is indicated in chronic adrenal cortical insufficiency (Addison's disease) and in adrenogenital salt-loss syndrome. Hypertension and advanced cerebral sclerosis are contraindications to the use of mineralocorticoids.

4.9.1. Cortexone

Cortexone [*64-85-7*], deoxycorticosterone, $C_{21}H_{30}O_3$, M_r 330.45, *mp* 141 – 142 °C, $[\alpha]_D^{22}$ + 178 ° (ethanol), is one of the most important mineralocorticoids.

Production. Three methods are used for the production of cortexone:

1) *Production from Pregn-5-en-3β-ol-20-one.* Pregnenolone (**106**) is subjected to Ruschig condensation with diethyl oxalate to give the sodium salt of the corresponding enol (**107**) [209], which is then converted with iodine to the iodine ester (**108**). Subsequent ketonic cleavage with sodium methoxide gives compound **109**, which yields the precursor (**110**) of cortexone on treatment with potassium acetate in aqueous acetone. A 71 % yield is obtained, based on compound **106** as starting material. Oppenauer oxidation of the 3β-hydroxyl group yields the 3-keto-Δ^4 group, and saponification of the 21-acetate group of **111** with 1 mol equivalent of sodium methoxide produces almost quantitative yields of cortexone (**112**).
   This synthesis can be carried out easily on a large scale because only two of the intermediates, compounds **108** and **110**, must be isolated.

2) *Microbiological Production from Progesterone.* Progesterone is specifically hydroxylated at position 21 by a microbiological method developed by Ciba, which uses fungal strains of scoleco spores, e.g., *Ophiobolus herbotrichus.* Cortexone (**112**) is formed with a yield of 60 % [233].
3) *Chemical Production from Progesterone.* In the commercially important process developed by Syntex, iodine reacts directly with progesterone in tetrahydrofuran – methanol in the presence of calcium carbonate to give 21-iodoprogesterone. The iodoprogesterone is then converted to cortexone 21-acetate (**111**) with potassium acetate in a mixture of acetic acid and acetone [234].

Trade Names. Cortexone is available under the following names: Cortenil depot (cyclopentylpropionate, Hoechst); Cortiron (acetate, Schering); Cortiron depot (heptanoate, Schering); Percoten (Ciba, Wehr).

4.9.2. Aldosterone

Aldosterone [*52-39-1*] (**79**), $C_{21}H_{28}O_5$, M_r 360.44, has the following properties: *mp* 108 – 112 °C (contains water of crystallization), *mp* 164 °C (anhydrous), $[\alpha]_D^{23}$ + 152.2 ° (anhydrous acetone).

Production. After the structure of aldosterone had been established, its total synthesis was achieved by WETTSTEIN, SZPILFOGEL, PRELOG, REICHSTEIN, and their coworkers. For a review of these syntheses, see [191].

The partial syntheses of aldosterone are of greater preparative importance [191]; however, only the most significant methods will be mentioned here. One method converts corticosterone acetate (corticosterone, see page 54) in four steps to aldosterone acetate [235]. Another method developed by Ciba starts with 11α-acetoxypregnenolone (cf. **106**), which is converted to compound **113** with lead tetraacetate and iodine and, after another 16 reaction steps, to aldosterone (**79**) [236].

The synthesis of aldosterone developed by VELLUZ and coworkers at Roussel-Uclaf is described in [237].
Trade Name. Aldosterone is marketed unter the trade name Aldocorten (Ciba, Wehr).

4.9.3. Spironolactone

Spironolactone [*52-01-7*] (**115**), $C_{24}H_{32}O_4S$, M_r 416.69, *mp* (double melting point) 134 – 135 °C and 201 – 202 °C, $[\alpha]_D^2$ – 33.5 ° (chloroform), the synthetic aldosterone antagonist, is of considerable therapeutic importance. It increases excretion of sodium and water, and is used as an oral saluretic. Treatment with aldosterone antagonists is indicated in cirrhosis of the liver with ascites and edema, water retention of cardiac and renal origin, hypertension resistant to antihypertonic agents containing saluretics, and in myasthenic and hypokalemic crises. Therapy is contraindicated in kidney insufficiency with anuria and hyperkalemia.

Production. The production of spironolactone from 17α-ethynylandrost-5-ene-3β,17β-diol (**114**) [238, 239] involves the following steps (Searle) [240]:

Trade Names. Spironolactone for oral administration is sold under the names Aldactone (Searle, Boehringer Mannheim) and Osyrol (Hoechst). Potassium aldadiene [*2181-04-6*] (**116**) is used for intravenous administration: Aldactone for injection (Searle, Boehringer Mannheim) and Osyrol for injection (Hoechst).

4.10. Chemically Modified Adrenal Steroid Hormones

A large number of chemically modified, highly potent corticosteroids have been prepared for therapeutic purposes by substitution or dehydrogenation reactions at positions 1, 2, 6, 9, 12, 16, and 21 of the corticosteroid skeleton. These compounds have greatly diminished the importance of naturally occurring cortisone derivatives with their severe mineralocorticoid side effects. However, despite intensive efforts, adequate reduction of the severe side effects that accompany systemic glucocorticoid therapy (e.g., Cushing's syndrome or osteoporosis) has not yet been achieved. The emphasis in corticoid therapy has changed from systemic administration to local or topical application because the associated side effects are then minor. A large number of corticoids have been developed for local or topical administration.

4.10.1. 1,2-Dehydrocorticosteroids

Introduction of a second double bond at the 1,2-positions of the cortisol molecule by HERSHBERG and coworkers of the Schering Corporation in 1955 represented a breakthrough in the synthesis of modified corticoids [241]. 1,2-Dehydrogenation yields derivatives with glucocorticoid, anti-inflammatory, and antiallergenic effects that are four to five times higher than those of cortisone. At the same time, these substances have one-third the mineralocorticoid activity of cortisone [242]. The 1,2-dehydro derivatives of cortisone and cortisol, *prednisone* (**117**) and *prednisolone* (**118**), respectively, do not have significant mineralocorticoid activity and are, therefore, widely used in general, systemic pharmacodynamic therapy, particularly as anti-inflammatory and antirheumatic agents.

Prednisone [*53-03-2*] (**117**), 1,2-dehydrocortisone, $C_{21}H_{26}O_5$, M_r 368.44, *mp* 233 – 235 °C, $[\alpha]_D^{25}$ + 172 ° (dioxane), and **prednisolone** [*50-24-8*] (**118**), 1,2-dehydrocortisol, $C_{21}H_{28}O_5$, M_r 360.44, *mp* 240 – 241 °C, $[\alpha]_D^{25}$ + 102 ° (dioxane), are the two most important 1,2-dehydrocorticosteroids.

Production. Insertion of the 1,2-double bond is achieved by chemical or microbiological methods, the latter being more economical. Prednisone can be produced chemically by

a process developed by the Schering Corporation from pregnane-17α,21-diol-3,11,20-trione 21-acetate (**119**) involving a 1,4-dibromide and subsequent hydrogen bromide elimination with pyridine [242]. Other methods use the 1,2-dehydrogenation of cortisone with selenium dioxide [243, 244].

119

The industrially important biological methods permit high-yield production of prednisone and prednisolone by microbiological dehydrogenation at the 1,2-positions of cortisone (**82**) and cortisol (**78**), respectively [245], with *Corynebacterium simplex* [246], *Rhizopus nigricans,* or *Bacillus subtilis* [247].

The chemical conversion of prednisone to prednisolone has also attained some commercial significance. This reaction proceeds via the 3,20-semicarbazone of prednisone and is very similar to the analogous conversion of cortisone to cortisol (see Section 4.8.3) [242].

Effects and Uses. Prednisone and prednisolone have four to five times the anti-inflammatory activity of cortisone when administered orally or parenterally, but only two to three times its activity when applied locally. In contrast, their mineralocorticoid potency is only one-third that of cortisone. The indications listed in Section 4.4 apply to both compounds, but prednisolone has become the "standard" corticoid in general practice. In comparison with cortisone and cortisol, the mineralocorticoid side effects are very slight.

Trade Names. A large number of commercial preparations are derived from prednisolone and prednisone; only a few examples are given here: Prednisolone: Decortin-H (Merck); Deltacortril (Pfizer); Hostacortin-H (Hoechst); Scherisolon (Schering); and Ultracorten-H (Ciba, Wehr).

Prednisone: Decortin (Merck); Hostacortin (Hoechst); Keteocort (Desitin, Hamburg); and Ultracorten (Ciba, Wehr).

4.10.2. 9α-Halocorticosteroids

In 1953 scientists at Syntex succeeded in inserting halogen atoms at the 9α-position of the cortisone molecule. The resulting modified corticoids had many times the glucocorticoid or anti-inflammatory activity of cortisone [215]. The glucocorticoid activity of hydrocortisones and cortisones with a halogen substituent at position 9α increases dramatically in the order: iodine, bromine, chlorine, fluorine. In comparison with cortisone acetate (activity = 1), the following activities are obtained for the 9α-halocorticoids in the liver glycogen test: I = 0.1, Br = 0.3, Cl = 5, F = 11. The value for 9α-fluorocortisone is 9. The mineralocorticoid effect also increases with the glucocorticoid activity; for example, 9α-fluorocortisol (**123**) has two to four times the mineralocorticoid activity of cortexone. Consequently, the halogen preparations have a very limited therapeutic applicability, despite their high glucocorticoid activities.

9α-Fluorocortisol [*127-31-1*] (**45**) is also known as fluorocortisone, $C_{21}H_{29}FO_5$, M_r 380.46, *mp* 260 – 262 °C, $[\alpha]_D^{23}$ + 139° (95 % ethanol).

Production. A method developed by Syntex uses 11α-cortisol 21-acetate (**120**) as the starting material [248]. This compound is converted to the 11α-tosylate, and subsequent elimination of the tosylate group with sodium acetate yields compound **121**. Stereospecific addition of hypochloric or hypobromic acid at the 9,11-double bond yields 9α-chloro- or 9α-bromocortisol 21-acetate, respectively. The 9,11β-epoxide (**122**) is obtained by treating the chloro- or bromohydrin with alkali. Introduction of fluorine or iodine at the 9α-position is achieved by cleavage of **122** with hydrofluoric or hydriodic acid (see upper one of next two figures).

Preparation of the corresponding 1,2-dehydrocorticoid, 9α-fluoroprednisolone (**124**), is described in [196]. The industrial and therapeutic significance of this compound has diminished (see lower one of next two figures).

120 **121**

122 9α-Fluorocortisol (**123**)

9α-Fluoroprednisolone (**124**)

Effects and Uses. Animal experiments have shown that 9α-fluorocortisol has almost 10 times the glucocorticoid or anti-inflammatory activity of cortisol, but its mineralocorticoid potency is approximately 15 – 20 times that of cortisone. 9α-Fluoroprednisolone has approximately 20 times the glucocorticoid potency of cortisol; its mineralocorticoid activity is the same as that of 9α-fluorocortisol.

9α-Fluorocortisol and its derivatives are primarily used locally in dermatology and ophthalmology in the form of ointments, cream, or drops. They are also used topically in rheumatology in the form of crystal suspensions for intraarticular injections. Oral substitution therapy in tablet form (0.1 mg per tablet) is indicated in cases of adrenogenital salt-loss syndrome and for raising blood pressure in constitutional hypotension (→ Antihypotensives, Chap. 3.2.).

Trade Names. The following trade names are used:

9α-Fluorocortisol: Astonin (Merck); Scherofluron (21-acetate, Schering); Florinef (Squibb).

9α-Fluoroprednisolone: Predef for veterinary medicine (21-acetate, Upjohn).

4.10.3. 16-Hydroxycorticosteroids

Scientists at Lederle succeeded in almost completely eliminating the mineralocorticoid side effects of 9α-fluoroprednisolone by introducing a 16α-hydroxyl group into the steroid nucleus [249]. Although the glucocorticoid and anti-inflammatory activities of 16α-hydroxycorticoids are approximately one-fifth those of 9α-fluoroprednisolone, they are still of tremendous therapeutic significance because they have practically no mineralocorticoid effects. A large number of derivatives have been obtained from the best known 16α-hydroxycorticoid, triamcinolone (**129**). The 16α,17α-acetonides have a much higher anti-inflammatory effect than the parent compounds. Surprisingly, they even exhibit a diuretic effect when pharmacologically tested for mineralocorticoid activity [250,251]. For this reason, the 16α,17α-acetonides are now indispensable in local corticoid therapy.

Triamcinolone [*124-94-7*] (**129**), $C_{22}H_{27}FO_6$, M_r 394.45, *mp* 269 – 271 °C, $[\alpha]_D^{25}$ + 75° (acetone) and **triamcinolone acetonide** [*76-26-5*] (**130**), also called triamcinolone 21, $C_{24}H_{31}FO_6$, M_r 434.49, *mp* 292 – 294 °C, $[\alpha]_D^{23}$ + 109° (chloroform), are the most important hydroxycorticosteroids.

Production. Triamcinolone (**129**) is prepared commercially via a method developed by Bernstein and coworkers [252]. By starting with cortisol 21-acetate (**91**), reaction with ethylene glycol gives the 3,20-bisethylene ketal (**125**). The 11β- and 17α-hydroxyl groups of this compound are then dehydrated with thionyl chloride in pyridine, followed by alkaline saponification of the 21-acetate group, acid deketalization of the cyclic acetal groups at positions 3 and 20, and reacetylation of the 21-hydroxyl group to yield compound **126**. Selective hydroxylation of the double bond at position 16 with osmium tetroxide in pyridine – benzene gives compound **127**. The 9,11-double bond of this compound is converted to a 9α-fluoro-11β-hydroxyl group (**128**) by the method described for 9α-fluorocortisol (**123**) in Section 4.10.2. Triamcinolone (**129**) is obtained after alkaline saponification of the 21-acetate group and microbiological introduction of the

Δ^1 double bond with *Corynebacterium simplex*. The total yield is not given in the literature.

The 16α-hydroxyl group can also be introduced directly into 9α-fluoroprednisolone (**124**) by using a microbiological method originally developed by Squibb [253, 254]. Triamcinolone 16α,17α-acetonide (**130**) is prepared by stirring a suspension of triamcinolone (**129**) in acetone in the presence of catalytic amounts of perchloric acid at approximately 20 °C until the steroid is completely dissolved. Yields of 95 % are obtained [255].

Effects and Uses. Systemic administration of 4 mg of triamcinolone produces the same effect as 5 mg of prednisolone or 25 mg of cortisol. Triamcinolone acetonide has 40 times the local anti-inflammatory activity of cortisol. Triamcinolone and its derivatives cause very low sodium and water retention, exert only a slight appetite-stimulating effect, but occasionally produce myopathy. Administration of these preparations is indicated particularly in patients who have a tendency to edema and who are over-weight.

Triamcinolone and its derivatives are applied systemically (oral, intravenous, or intramuscular), topically (intraarticular as a crystal suspension), and locally (ointment, cream, or lotion).

Trade Names. The following trade names are used:

Triamcinolone (chiefly for systemic application): Delphicort, Aristocort (Lederle); Volon (Heyden); Kenacort (Squibb). Triamcinolone 21-(3,3-dimethylbutyrate), also called triamcinolone hexacetonide (for topical long-term therapy): Aristophan (Lederle). Triamcinolone 16,17-diacetate (for topical therapy): Delphicort (Lederle).

Triamcinolone acetonide (for topical therapy): Volon-A (Heyden); Delphicort (Lederle). Triamcinolone acetonide is used as its 21-disodium phosphate in Aristosol and as its 21-hemisuccinate in Solutedarol for systemic intravenous administration.

4.10.4. 6α-Methylcorticosteroids

Insertion of a 6α-methyl group into the corticosteroid nucleus by scientists at Upjohn [256] and British Drug Houses [257] gave rise to derivatives with enhanced glucocorticoid activity and low mineralocorticoid activity. The most potent orally, parenterally, and topically active compounds are 6α-methylprednisolone (**131**), which has approximately 10 times the anti-inflammatory activity of cortisol in animal experiments, and 6α-methyl-9α-fluoroprednisolone (**132**), which has relatively low mineralocorticoid activity and almost 100 times the glucocorticoid potency of cortisol in animal experiments. 21-Deoxy-6α-methyl-9α-fluoroprednisolone (**133**) is important in the local treatment of inflammatory skin diseases.

131: X = H, R = OH
132: X = F, R = OH
133: X = F, R = H

6α-Methylprednisolone [*83-43-2*] (**131**), $C_{22}H_{30}O_5$, M_r 374.46, *mp* 228–237 °C, $[\alpha]_D^{20}$ +83° (dioxane), and **21-deoxy-9α-fluoro-6α-methylprednisolone** [*426-13-1*] (**133**), fluorometholone, $C_{22}H_{29}FO_4$, M_r 376.47, *mp* 292–303 °C, are the most important 6α-methylcorticosteroids.

Production. 6α-Methylcorticoids are prepared commercially from 11α-hydroxyprogesterone (**83**), as shown below [256]:

Compound **83** is treated with ethylene glycol to give the 3,20-bis(ethylene ketal). The 6-methyl group is then introduced into the epoxide (**135**) by the Grignard reaction. The 11α-hydroxyl group of compound **136** is subsequently oxidized with chromic acid to give the 11-keto function, and compound **137** is finally obtained after deketalization, dehydration, and isomerization. The 17-acetyl group of compound **137** is then converted to the 17-dihydroxyacetone side chain by using the progesterone method (see Section 4.8.2). The 11-keto group is reduced to an 11β-hydroxyl group, and introduction of the Δ^1 double bond finally leads to 6α-methylprednisolone (**131**).

Another method developed by Merck, Sharp, and Dohme uses cortisone as the starting material. Cortisone is first converted to the 6-keto derivative via suitable intermediates. Subsequent Grignard reaction with methylmagnesium bromide and further reaction steps then yield 6α-methylprednisolone [258].

In the production of 6α-methyl-21-deoxycorticosteroids, the corresponding 11-deoxy-21-hydroxylated compounds are used as starting materials because they can easily be hydroxylated microbiologically at position 11. After 11-hydroxylation, the 21-hydroxyl group is first replaced with an iodine moiety, via the tosylate or mesylate, and then reduced with hydrogen [259]. Preparation of 21-deoxy-6α-methyl-9α-fluoroprednisolone (**133**) is described in [260].

Effects and Uses. 6α-Methylprednisolone (4 mg of which is equivalent to 5 mg of prednisolone) is well tolerated by the stomach, has no mineralocorticoid side effects, and is the corticoid of choice for systemic long-term therapy. It increases appetite slightly and is mildly stimulating psychologically.

6α-Methylprednisolone is administered orally, intravenously (as a water-soluble solution of the 21-sodium hemisuccinate), or topically (as a crystal suspension). Its 21-cyclopentylpropionate derivative is most suitable for intramuscular application and has an extremely long duration of action. Fluorometholone (**133**) is a strong anti-inflammatory substance and is used exclusively in the form of ointments, creams, and lotions in the local treatment of dermatosis.

Trade Names. The following trade names are employed:

6α-Methylprednisolone (for oral application): Urbason (Hoechst); Medrate (Upjohn); Medrol (Upjohn).

6α-Methylprednisolone 21-acetate (for topical application): Urbason crystal suspension (Hoechst); Depo-Medrol (Upjohn).

6α-Methylprednisolone 21-sodium hemisuccinate (for intravenous application): Urbason soluble (Hoechst); Medrate soluble (Upjohn); Solu-Medrol (Upjohn).

6α-Methylprednisolone 21-cyclopentylpropionate (for intramuscular application with long-term effects): Urbason Depot (Hoechst).

21-Deoxy-6α-methyl-9α-fluoroprednisolone (for local application): Delmeson (Hoechst); Oxylone (Upjohn).

4.10.5. 16-Methylcorticosteroids

Introduction of a methyl group at the 16α-position of the corticoid molecule greatly increases glucocorticoid and anti-inflammatory activity, and decreases mineralocorticoid activity [261]. 16α-Methylcorticosteroids include 16α-methylhydrocortisone, 16α-methylprednisolone and 16α-methyl-9α-fluoroprednisolone. The last mentioned, also known as *dexamethasone* (**141**), has very low mineralocorticoid activity and approximately 30 – 40 times the anti-inflammatory potency of hydrocortison. It is, therefore, highly effective when given orally, parenterally, or locally in the treatment of inflammatory, rheumatic, and allergic diseases.

The corresponding 16β-*methylcorticosteroids* also possess high glucocorticoid activity and exert only a slight effect on mineral metabolism. Their anti-inflammatory activity is equal to that of the 16α-methylcorticoids. *Betamethasone* (**68**) [262–264], 16β-methyl-9α-fluoroprednisolone, was developed by the Schering Corporation and, like dexamethasone, is of great importance in oral, parenteral, and local therapy.

Dexamethasone [*50-02-2*] (**141**), 9α-fluoro-16α-methylprednisolone, $C_{22}H_{29}FO_5$, M_r 392.45, *mp* 262 – 264 °C, $[\alpha]_D^2$ +77.5°, and **betamethasone** [*378-44-9*] (**146**), 9α-fluoro-16β-methylprednisolone, $C_{22}H_{29}FO_5$, M_r 392.45, *mp* 231 – 234 °C, $[\alpha]_D$ +108° (acetone), are representative of the 16-methylcorticosteroids.

Production. A number of multistage procedures for the synthesis of *dexamethasone* have been developed, mainly by Merck [261], Schering [265], Roussel-Uclaf [266], and Upjohn [269]. The Schering method uses 16-methylpregna-4,16-dien-3β-ol-20-one (**138**) as the starting material (Fig. 10). This compound is obtained by copper(II)-catalyzed 1,4-addition of methylmagnesium bromide to the Δ^{16}-20-keto system of 16-dehydropregnenolone (**92**) [267].

Figure 10. Production of dexamethasone (**141**) from 16-methylpregna-4,16-dien-3β-ol-20-one (**138**)

Stereospecific catalytic hydrogenation of the double bonds at the 3,4- and 16,17-positions of compound **138** yields 16α-methyl-3β-hydroxy-5α-pregnan-20-one. Compound **139** is obtained by the stereospecific introduction of a 17α-hydroxyl group into the $\Delta^{17,20}$-20-enolacetate with peracetic acid. The 21-acetate group is then inserted via the 21-bromide. The next steps involve oxidation of the 3β-hydroxyl group with

chromium trioxide to the 3-keto group, dibromination in the α,α'-position to give the α,α'-dibromo derivative, elimination of the bromine groups to yield the $\Delta^{1,4}$-dien-3-one system, and alkaline saponification of the 21-acetate group. Compound **140** is then obtained microbiologically by introduction of the required oxygen function at the 11α-position.

The 11α-hydroxyl compound is converted to the 9α-fluoro-11β-hydroxyl derivative as described in Section 4.10.2. Alkaline saponification of the 21-acetate group finally produces dexamethasone (**141**).

The Merck [261] method involves the preparation of 16-pregnen-3α-ol-11,20-dione 3-acetate (**142**), as described in [268]. This compound already has the essential oxygen function at position 11. Conversion to dexamethasone (**141**) requires 14 further reaction steps.

142

Similar concepts have been developed for the industrial production of *betamethasone* by Merck [270], Schering [271], and Roussel-Uclaf [272].

The 16β-methyl group is inserted into the appropriate precursor. The Merck method uses 3α-acetoxy-16-pregnene-11,20-dione (**142**) as the starting material [273]. A 1,3-dipolar addition reaction with diazomethane at the double bond between positions 16 and 17 gives compound **143**. Alkaline cleavage or pyrolysis at ca. 200 °C then leads to the homologous 16-methyl-16-dehydro-20-keto compound (**144**). Stereospecific, catalytic hydrogenation of the Δ^{16} double bond with palladium and calcium carbonate yields compound **145**, which has a β-methyl group at position 16. The other essential groups (the 17α- and 21-hydroxyl groups, and the 9α-fluoro group) and the dienone structure in ring A are then introduced in a series of steps to give betamethasone (**146**).

Effects and Uses. A dose of 1 mg of dexamethasone or betamethasone is equivalent to 5 mg of prednisolone or 20 mg of cortisol.

Of all the corticoids used in medicine, dexamethasone and betamethasone exert the strongest glucocorticoid and anti-inflammatory effects. However, these compounds not only have a high glucocorticoid potency, they also have a number of unpleasant side effects that must be considered, especially in systemic therapy. Both compounds are very psychologically stimulating (euphoria) and increase appetite. Other unfavorable side effects include high catabolic activity, strong hypophyseal inhibition, and considerable calcium and phosphate excretion leading to osteoporosis. For these reasons, both of these highly potent corticoids are more suitable for limited, pharmacodynamic therapy than for long-term treatment. Betamethasone is slightly better tolerated by the stomach than dexamethasone.

Trade Names. The following are some trade names for these two compounds:

Dexamethasone and derivatives (21-acetate, 21-trimethylacetate, 21-disodium phosphate, 21-sodium hemisuccinate, 21-isonicotinate): Decadron (Sharp and Dohme); Fortecortin (Merck); Millicorten (Ciba); Auxiloson (Thomae); Dexa-Scheroson (Schering); Oradexon (Organon); Dexa-Cortidelt (Roussel-Pharma); Dexamethason "Ferring" (Ferring); Dexonil (Schering).

Betamethasone and derivatives (as above) for systemic, topical, and local therapy: Betnesol (Glaxo); Celstone (Schering); Celestan (Byk-Essex) Derivatives for local therapy include betamethasone 17-valerate [Bentnesol V (Glaxo); Celestan V (Byk-Essex) and betamethasone 17,21-dipropionate [Dipcosone (Schering)]. 9α-Chloro-16β-methylprednisolone 17,21-dipropionate [*4419-39-0*], also

known as beclomethasone, is especially suitable for local therapy: Propaderm, production is described in [274,275].

4.10.6. 16-Methylenecorticoids

Animal experiments have shown that insertion of a 16-methylene group into the prednisolone nucleus enhances glucocorticoid activity. 16-Methyleneprednisolone, prednylidene (**147**), has an almost total absence of mineralocorticoid activity. Substitution at the 9α-position with fluorine leads to the local corticoid fluprednylidene [*2193-87-5*] (**148**).

147: X = H
148: X = F

16-Methyleneprednisolone [*599-33-7*] (**147**), prednylidene, $C_{22}H_{28}O_5$, M_r 372.44, *mp* 233–235 °C, $[\alpha]_D^{23}$ +31 ° (dioxane), is produced as described below.

Production. The 16-methylene-17-dihydroxyacetone group of the 16-methylenecorticoids is achieved by using the following reaction sequence [276–278]:

149 **150** **151** **152**

The addition of alkaline hydroperoxide to the double bond at the 16,17-positions of the 16-methyl-16-dehydro-20-keto system (**149**) of a suitable pregnane derivative stereospecifically produces the 16α,17α-oxide (**150**). Treatment with toluene-*p*-sulfonic acid in acetone then leads to opening and isomerization of compound **150**, giving the 17α-hydroxyl and 16-methylene groups (**151**). Insertion of a 21-hydroxyl group by conventional means gives the complete 16-methylene-17-dihydroxyacetone structure (**152**). Both prednylidene (**147**) and fluprednylidene (**148**) are synthesized in this way.

Effects and Uses. A dose of 9 mg of 16-methyleneprednisolone is equivalent to 7.5 mg of prednisolone or 30 mg of cortisol. Prednylidene, which is slightly less potent than prednisolone in humans, is similar to 6α-methylprednisolone in that it is very mildly, psychologically stimulating, only slightly stimulating to the appetite, well tolerated by the stomach, and suitable for long-term therapy. Fluprednylidene is more active when applied locally and is used exclusively in local corticoid therapy because of its strong mineralocorticoid activity.
Trade Names. Prednylidene is used primarily in systemic therapy as such or as the water-soluble 21-diethylaminoacetate hydrochloride: Decortilen (Merck).

Fluprednylidene is used exclusively in local corticoid therapy as the 21-acetate: Decoderm (Merck).

4.10.7. 6α-Fluoro-, 6α-Chloro-, and 6α,9α-Difluorocorticoids

Insertion of fluorine or chlorine into the 6α-position of the steroid skeleton increases glucocorticoid potency and eliminates mineralocorticoid activity [279]. Here again, the 6α-fluoro derivatives have a stronger anti-inflammatory effect than the homologous chlorine compounds.

6α-Fluoroprednisolone (**153**), also called fluprednisolone, has approximately the same glucocorticoid activity as triamcinolone. Insertion of other activating groups into the 6α-fluoroprednisolone molecule (primarily a methyl or a hydroxyl group at position 16 or another fluoro group at position 9α) strikingly enhances glucocorticoid activity. However, the undesirable mineralocorticoid side effects also increase. Insertion of a 16α-methyl group into the fluprednisolone molecule yields systemically active paramethasone (**154**). 6α,9α-difluoro-16α-methylprednisolone (**155**), flumethasone, has not only the 6α-fluoro group, but also the

strongly activating 9α-fluoro and 16α-methyl groups. The 16,17-acetonides (**156**) are also widely used. The following are some therapeutically important compounds:

6α-Fluoroprednisolone [*53-34-9*] (**153**), fluprednisolone, $C_{21}H_{27}FO_5$, M_r 378,45, *mp* 208 – 213 °C

Paramethasone [*53-33-8*] (**154**), $C_{22}H_{29}FO_5$, M_r 392.45, 21-acetate: *mp* 228 – 241 °C

Flumethasone [*2135-17-3*] (**155**), $C_{22}H_{28}F_2O_5$, M_r 410.46

Fluocinolone acetonide [*67-73-2*] (**156**), $C_{24}H_{30}F_2O_6$, M_r 452.50, *mp* 265 – 266 °C, $[\alpha]_D$ +95 ° (chloroform)

6α-Fluoro-16α-hydroxycortisol (**158**), fluandrenolone, $C_{21}H_{29}FO_6$, M_r 396.46, *mp* 234 – 236 °C, $[\alpha]_D$ +95 ° (dioxane)

153: X = Y = Z = H
154: X = Y = H; Z = CH_3
155: X = F; Y = H; Z = CH_3
156: X = F; Y and Z = 

157: X = H
158: X = OH

Production. 6α-*Fluorocortisol* (**157**) is prepared from 3β,17α,21-trihydroxypregn-5-en-20-one 17,21-diacetate [280] with a method developed by Syntex [281]. This compound has no therapeutic importance but typifies insertion of the 6α-fluoro group.

A method developed by Syntex [282] is used to synthesize the therapeutically important compound *paramethasone* (**154**). The double bond at the 5,6-positions of the starting compound, 16α-methylpregnenolone 3-acetate (**159**), is converted stereospecifically with perbenzoic acid to the 5,6α-oxide (**160**). Compound **160** is then cleaved with boron trifluoride to give the 6β-fluoro-5α-hydrin (**161**). After insertion of the 17α- and 21-hydroxyl groups, oxidation with chromium trioxide, and dehydration to the 3-keto-4,5-dehydro system (**162**), the 6β-fluoro group is isomerized to the 6α-fluoro group by treatment with acid. The 11β-hydroxyl group is then inserted enzymatically by incubation with bovine adrenal gland [283], to give a yield of 50 – 60 %. Product **163** is dehydrogenated with selenium dioxide in *tert*-butanol and pyridine to yield paramethasone (**154**).

Compound **163** also serves as an intermediate in the commercial synthesis of the local corticoid *flumethasone* (**155**) as follows:

1) dehydration of **163** with $SOCl_2$ and pyridine to give the $\Delta^{9,11}$ derivative;
2) formation of the 9,11β-oxide, as described in Section 4.10.2;

3) cleavage with hydrogen fluoride to give the 9α-fluoro,11β-hydroxy derivative; and
4) dehydrogenation with selenium dioxide to $\Delta^{1,2}$.

Fluprednisolone (**153**) is synthesized with methods developed by Upjohn [284], Syntex [285], and Bayer [286]. *Fluocinolone acetonide* (**156**) is important in local therapy and can be prepared commercially from 16α,17α-oxidopregn-5-ene-3β,21-diol-20-one 21-acetate (made according to [287]) via fluandrenolone (**158**) in a multistage process (more than 20 reaction steps) [288].

In addition to the cleavage of 5,6α-oxy groups with hydrofluoric acid, other methods have been elaborated to insert the 6α-fluoro group into the corticoid nucleus. In a method developed by Syntex, FBr (from hydrofluoric acid and *N*-bromosuccinimide) is added to the Δ^5 double bond of compound **164**, forming the corresponding 5α-bromo-6β-fluoro compound (**165**). Subsequent oxidation of the 3-hydroxyl group with chromium trioxide gives the 3-oxo group, and elimination of hydrogen bromide produces 6β-fluoro-Δ^4-3-keto steroids (**166**). Acid isomerization of the 6β-fluoro group yields 6α-fluoro-Δ^4-3-keto steroids [279, 289].

The 6-fluoro group can also be inserted by converting the $\Delta^{3,5}$-3-enolacetates of suitable pregnane precursors with perchloryl fluoride ($FClO_3$) in dioxane as solvent [290].

Similarly, the 6α-chlorine atom can be inserted into the steroid skeleton by reacting the $\Delta^{3,5}$-3-enolethers or Δ^5-3-ethylene dioxysteroids with *N*-chloroacetamide [291].

Effects and Uses. A systemic dose of 2.5 mg of fluoroprednisolone or 2.0 mg of paramethasone is equivalent to 5.0 mg of prednisolone. Both corticoids are used in systemic therapy; they are well tolerated by the stomach and suitable for short- or long-term treatment. However, the relatively strong hypophyseal inhibition exerted by both corticoids must be taken into consideration.

The highly active local corticoids flumethasone and fluocinolone acetonide are widely applied as the free 21-alcohols or their esters in local corticoid therapy. They are not administered systemically.

Trade Names. The following trade names are used:

Fluprednisolone (systemic administration): Alphadrol (Upjohn).

Paramethasone (systemic administration as the 21-acetate or 21-disodium phosphate): Monocortin (Grünenthal); Stemex (Syntex); Haldrone (Lilly).

Flumethasone (applied locally as the 21-pivalate): Locacorten (Ciba and Syntex).

Fluocinolone acetonide (for local application): Jellin (Grünenthal); Synalar (Syntex); Lidex (21-acetate, Syntex).

4.10.8. 17-Deoxycorticosteroids

In 1964 Raspé and coworkers found that 16α-methylcorticosteroids lacking the 17α-hydroxyl group are still relatively strong anti-inflammatory substances with very low mineralocorticoid activity [292]. For instance, 16α-methyl-1-dehydrocorticosterone has approximately the same anti-inflammatory activity as prednisolone when applied locally, subcutaneously, or orally. 6α-Fluoro-16α-methyl-1-dehydrocorticosterone, fluocortolone (**169**) is used in systemic corticoid therapy [293]. The similarly structured 9α-fluoro-16α-methyl-1-dehydrocorticosterone, desoximetasone (**173**), is commercially available as a highly active local corticoid [294].

Fluocortolone [*152-97-6*] (**169**), $C_{22}H_{29}FO_4$, M_r 376.47, *mp* 188 – 190.5 °C, $[\alpha]_D^{20}$ +100° (dioxane), and **17-desoximetasone** (**173**), $C_{22}H_{29}FO_4$, M_r 376.47, *mp* 217 °C,

$[\alpha]_D^{20} + 109°$ (chloroform), are important 17-deoxycorticosteroids.

Production. *Fluocortolone* (**169**) is prepared from 16α-methylpregn-5-ene-3β,21-diol-20-one 21-acetate (**167**) (obtained as described in [295]) in a method developed by Schering [293, 296]. 6α-Fluoro-16α-methyldeoxycorticosterone (**168**) is formed in a reaction sequence analogous to **164** → **166**, with subsequent isomerization. The 11β-hydroxyl group is introduced microbiologically by using *Curvularia lunata* [297], followed by stereospecific dehydrogenation at the 1,2-positions with *Corynebacterium simplex* [298] or *Bacillus lentus* [299] and saponification of the 21-acetate group to yield fluocortolone (**169**).

167

168

169

Desoximetasone (**173**) is prepared from compounds **170** or **171** according to two different methods developed by Roussel – Uclaf [294, 300]. These processes require six and eight reaction steps, respectively, to produce the important intermediate **172**, which is then converted to desoximetasone (**173**) in four further steps:

Effects and Uses. A systemic dose of 7.5 mg of fluocortolone is equivalent to 7.5 mg of prednisolone. Although fluocortolone is a corticosterone derivative, it exerts the same systemic glucocorticoid and anti-inflammatory effects in humans as prednisolone. It is well tolerated by the stomach, exhibits only slight catabolic activity, and is thus highly suitable for long-term treatment. In addition, fluocortolone is a powerful local anti-inflammatory substance and, consequently, is used in local corticoid therapy. Because 17-desoximetasone has an unusually high local anti-inflammatory activity, it is an excellent local corticoid.

Trade Names. The following trade names are used:

Fluocortolone (systemic, local, and topical): Ultralan (Schering). It is used locally as such, as the 21-trimethylacetate, as the 21-capronate, or as a mixture of these compounds.

17-Desoximetasone (local): Topisolon (Hoechst); Topicort (Roussel).

Chlorocortolone [*4828-27-7*] (**174**) is another 17-deoxycorticoid that has a chlorine atom at position 9α and a fluorine atom at position 6α. This compound is prepared by a method patented by Schering and is used exclusively in local corticoid therapy [301].

Trade Name. Chlorocortolone is applied locally as the 21-trimethylacetate or 21-capronate: Kaban (Asche, Hamburg).

4.10.9. 9α,11β-Dihalocorticosteroids

Scientists at Schering found that the oxygen at position 11 in corticosteroids can be replaced by a halogen without loss of glucocorticoid or anti-inflammatory activity. Thus 9α,11β-dichloroprednisolone (**175**), also called dichlorisone, not only has a very low mineralocorticoid activity but also has ten times the anti-inflammatory activity of prednisolone [302]. It was launched on the market as the 21-acetate.

Dichlorisone [*7008-26-6*] (**175**), $C_{21}H_{26}Cl_2O_4$, M_r 413.35, has the following properties: *mp* 238 – 241 °C, $[\alpha]_D^{20}$ + 134 ° (pyridine).

Production. The synthesis of dichlorisone involves selective addition of equimolar amounts of the desired halogens to steroids with a double bond at position $\Delta^{9,11}$ [302, 303].

Dichlorisone (**175**)

Effects and Uses. In animal experiments, dichlorisone has ten times the anti-inflammatory potency of prednisolone. The 9α,11β-dichlorocorticoids have not been used in systemic therapy because they exert exceptionally strong (specific) glucocorticoid effects (Cushing's syndrome). However, they also have a strong local and topical anti-inflammatory effect. Dichlorisone is especially useful in local antipruritic therapy.

Trade Names. Dichlorisone is used for topical and local therapy only: Diloderm, Disoderm (Schering).

4.11. Other Developments

Extensive efforts to obtain better separation of systemic and topical effects have produced a series of new preparations with little or no systemic activity. Therefore, these compounds are especially suitable for treating dermatosis in children and large cutaneous areas. These preparations are derivatives of known, active corticoids.

6α-Methylprednisolone aceponate [*83-43-2*] (Schering AG) [4.122]

Fluocortin butyl [*41767-29-7*] (Vaspit, Schering AG) [4.119]

Prednicarbate [*73771-04-7*] (Hoe 777, Hoechst) [4.121]

Alclometasone dipropionate [*66734-13-2*] (Delanol, Modrasone, Schering Corp.) [4.123]

Beclomethasone dipropionate [*5534-09-8*] (Sanasthmyl, Glaxo) [4.118]

Budesonide [*51333-22-3*] (Pulmicort, Astra) [4.120]

Fundamentally new preparations or replacement of corticoids with another class of substances is not in sight. Improvements are to be found in application protocols (the circadian rhythm is taken into account) and in the wide range of galenical preparations.

5. Cholecalciferol

5.1. Introduction

Cholecalciferol [*67-97-0*] (vitamin D_3) is formed by UV irradiation of 7-dehydrocholesterol in the skin [310]. In 1971, DeLuca and coworkers succeeded in identifying 1α,25-dihydroxyvitamin D_3 [*32222-06-3*] (calcitriol) as the basic active principle formed by consecutive hydroxylation of vitamin D_3 in the liver and kidney [311]; it functions as a regulator of calcium and phosphate transport.

Cholecalciferol and its biologically active metabolite calcitriol must be classified as hormones rather than as vitamins (i.e., substances in food required for normal development). However, certain vitamin D deficiencies can be treated by diets containing vitamin D_3 or D_2.

Historical Aspects. The first description of rickets, a vitamin D deficiency disease, dates to antiquity. During the Industrial Revolution the incidence of rickets increased to epidemic proportions, especially in Europe and North America. The systematic search for an antirachitic factor in food began around 1920, stimulated by the observation that the disease could be cured by either UV irradiation or the intake of fish-liver oil [312]. A major breakthrough was achieved when vitamin D_2 [*50-14-6*] (ergocalciferol) was identified as a potent antirachitic principle that could be obtained by irradiating natural ergosterol [313,314]:

Ergosterol

Vitamin D_2

Although vitamin D_2 occurs naturally (in fish-liver oil), it proved nonidentical with the factor produced by photochemical conversion in the skin of mammals. Windaus and coworkers succeeded in identifying and synthesizing vitamin D_3 as the natural principle formed by photolysis of 7-dehydrocholesterol [315,316].

5.2. Biosynthesis and Metabolism

The metabolism of vitamin D_3 is summarized in Figure 11. In a reaction catalyzed by UV light (wavelength 250 – 300 nm), 7-dehydrocholesterol accumulates in the skin and is transformed into previtamin D_3 which undergoes isomerization to vitamin D_3 by a thermal 1,7-hydrogen shift [317].

Alternatively, dietary vitamin D_3 is taken into the bloodstream by the intestinal route. A specific vitamin D_3 binding protein transports vitamin D_3 to the liver where a cytochrome P450 enzyme hydroxylates the compound at position C-25 to yield 25-hydroxyvitamin D_3. In the kidney, another cytochrome P450 steroid hydroxylase (1α-hydroxylase) introduces a hydroxyl group at position C-1 to form the active

Figure 11. Metabolism of vitamin D_3

metabolite 1α,25-dihydroxyvitamin D_3 (calcitriol). This step appears to be modulated by parathyroid hormone [310, 318]. Calcitriol is bound with high affinity to a specific protein receptor (1α,25-dihydroxyvitamin D_3 receptor, M_r 50 000 – 60 000), which binds to DNA. 1α,25-Dihydroxyvitamin D_3 receptors have been detected in many tissues (intestine, bone, pancreas, thyroid, muscle, gonads).

Calcitriol is inactivated by further enzymatic hydroxylation and oxidation. Approximately 20 metabolic derivatives of calcitriol have been found in human and animal tissue, all of them considerably less active than 1α,25-dihydroxyvitamin D_3.

5.3. Biological Activity

DeLuca and coworkers demonstrated that the biological activity previously ascribed to vitamine D_3 was actually produced by 1α,25-dihydroxyvitamin D_3 (calcitriol).

Calcitriol stimulates bone growth and mineralization by increasing the intestinal absorption of calcium and phosphate, thereby maintaining the necessary serum levels. The discovery of 1α,25-dihydroxyvitamin D_3 receptors in bone indicates a direct action of calcitriol on calcium transport in bone tissue. Bone undergoes constant remodeling; both synthesis and resorption are influenced by calcitriol in a dose-dependent manner. Calcitriol can be used to treat rickets and osteomalacia (softening of the bones), and is indispensable in the treatment of chronic renal failure. Controversy still exists as to whether osteoporosis in postmenopausal women is amenable to calcitriol therapy.

In addition to its effects on mineral homeostasis, 1α,25-dihydroxyvitamin D_3 influences cell proliferation and differentiation in tissues not related to the classical sites of action (intestine, bone, kidney). The irregular growth and maturation of epidermal cells (a symptom of psoriasis) can be inhibited by topical adminis-

tration of calcitriol. Inhibitory effects have been demonstrated for various cancer cell lines, so that calcitriol and its derivatives may find new therapeutic uses [310, 318].

5.4. Chemical Synthesis

Following the pioneering work of WINDAUS and coworkers [314, 315], numerous research groups have been engaged in the synthesis of vitamin D_3, its hydroxylated metabolites, and analogues [319].

Classical photolysis of a steroidal 5,7-diene precursor remains the basis for several recent strategies, although other nonphotochemical concepts are being developed. The principle of convergence (i.e., separate construction of major molecular portions that are combined in a final step to form the structural entity) appears to be a promising approach to an economical, large-scale production of vitamin D_3 and derivatives.

Examples are given for two calcitriol syntheses based on the classical concept [320] and the convergent strategy [321].

Classical Concept. BARTON et al. started their synthesis of calcitriol with 25-hydroxycholesterol (**176**) [320]. Dehydrogenation with dichlorodicyano-*p*-benzoquinone gave the trienone **177**, which was selectively epoxidized to form the $1\alpha,2\alpha$-epoxide **178**. Lithium–ammonia reduction of **178** followed by acetylation yielded the triacetate **179**, which was transformed to the key intermediate **180** by allylic bromination–dehydrobromination. Electrocyclic ring opening by irradiation via the intermediate **181**, thermal isomerization, and saponification resulted in the formation of 1α,25-dihydroxyvitamin D_3 (calcitriol; see right figure).

Convergent Strategy. USKOKOVIC and coworkers achieved a highly stereoselective, total synthesis of calcitriol by combining synthons **182** and **183**, prepared from easily accessible chiral starting materials, in a Wittig–Horner reaction as the final step [321] (see figure on top of next page).

5.5. Synthetic Analogues

Numerous attempts have been made to find derivatives of vitamin D_3 and 1α,25-dihydroxyvitamin D_3 with better separation of the systemic effect on calcium metabolism and the antiproliferative, cell-differentiating activities [322]. Fluorination at position C-24, C-26, or C-27 substantially increases potency, compared with fluorine-deficient compounds. Other chemical modifications have led to derivatives with much lower activity, so that synthetic efforts in this field continue [322].

Abstract | Full Text: **HTML**

Abstract

The article contains sections titled:

1. Introduction
2. Functions of Hydraulic Fluids
3. Parameters to Describe the Properties
4. Additives to Hydraulic Fluids
5. Types of Hydraulic Fluids
5.1. Mineral Oils for Hydrostatic Machines
5.2. Mineral Oils for Hydrokinetic Systems
5.3. Mineral Oils as Multipurpose Oils
5.4. Aircraft and Marine Hydraulic Fluids
5.5. Fire-Resistant Hydraulic Fluids
5.6. Brake Fluids
5.7. Environmentally-Friendly Hydraulic Fluids
6. Various Aspects of the Use of Hydraulic Fluids

[Top of Page]

1. Introduction

Hydraulic fluids transmit energy in fluid-filled, pressurized systems. The hydraulic energy is transferred from the generating section, (the hydraulic pumps) to the motor section (the hydraulic motors, actuating cylinders, or turbines). The quantity, pressure, and direction of flow of the fluid are controlled by valves. Basically, two types of hydraulic principles can be distinguished: hydrostatic and hydrokinetic drives.

Hydrostatic drives utilize the fact that the pressure in a fluid is distributed evenly in all directions and thus displaces the fluid into closed but changing spaces. The pump displaces a certain volume of hydraulic fluid per stroke or revolution against the pressure in the system (hydraulic motor or actuating cylinder). The main areas of application of hydrostatic drives are (1) construction machinery, (2) machine tools, (3) tractors and agricultural equipment, (4) materials-handling technology, (5) aviation, (6) processing machinery, and (7) auxiliary drives and braking equipment in vehicles.

Hydrokinetic drives work with the kinetic energy of the flowing hydraulic fluid. Usually a generator (pump) and a motor (turbine) are positively connected to one another by the fluid stream in the most confined space possible. If there is a difference in the rotational speeds of the pump and the turbine an impulse exchange takes place and energy is transmitted to the slower impeller.

Hydrokinetic drives are found in road and rail vehicles and in marine applications. The fluids used in these cases are known as *power transmission fluids, automatic transmission fluids* (ATF), or *hydraulic gear oils.*

[Top of Page]

2. Functions of Hydraulic Fluids

The most important function of a hydraulic fluid is, of course, energy transfer. However, to ensure trouble-free operation hydraulic fluids have to perform a series of other functions.

Energy Transfer. It is important for pressure transmission that the volume (and, thus, density) of a hydraulic fluid does not change under pressure, i.e., the compressibility must be low. The flow properties (viscosity) should also be largely independent of pressure.

Lubrication. A good hydraulic fluid lowers the friction between moving sliding parts and reduces wear. Especially for reciprocating parts it is important that the fluid has a good load-carrying capacity at the reversal points.

Cooling. Unavoidable power dissipation in a hydraulic drive leads to an increase in temperature of the system. Effective heat removal improves the efficiency of a machine. A hydraulic fluid with a high specific heat and a low viscosity (low internal friction) makes a particular contribution here.

Corrosion Protection. Steel or nonferrous metal surfaces must be protected against corrosion, including periods of fairly long downtime. Changes in the hydraulic fluid during use, that are caused by oxygen, heat, water, etc., must not reduce the corrosion protection.

System Cleanliness. Precision hydraulic machines, e.g., servo valves contain control systems with gap widths of less than 1 µm. Oil-insoluble products, such as dust, abrasive particles, or high-molecular oxidation products, must not produce any deposits in the control equipment. The equipment functions at its best if the foreign matter is held in suspension and carried through to the filter system.

3. Parameters to Describe the Properties (→ Lubricants and Lubrication)

In addition to the "conventional parameters," (color, flash point, total acid number, TAN, etc.) the "operating properties" must also be known to achieve trouble-free operation of a hydraulic machine. These include those properties (expressed by parameters) which are important for the projected use of the hydraulic fluid and properties which may change during use.

Viscosity (ASTM D445, IP71, DIN 1342, 51 550, 51 562, 5 015). A suitable viscosity is the most important criterion when selecting a hydraulic fluid. This is determined by the design of the hydraulic system and is governed to a great extent by the requirements of the hydraulic pumps or motors [1]. In order to achieve low flow losses and very high precision during control operations a hydraulic liquid should have the minimum viscosity accepted by the equipment manufacturer. Table 1 lists some guide values for maximum permissible initial and minimum permissible operating viscosities for various types of hydraulic pump [2]. At the *highest operating temperature* the kinematic viscosity should not fall below 5 mm^2/s. Exceptions are water-based hydraulic systems so-called pressurized-water systems. At low viscosities the wear increases quickly and the efficiency of the hydraulic plant decreases rapidly. At *low temperatures* hydraulic pumps will only draw in hydraulic fluid up to viscosities of approximately 1000 mm^2/s.

Table 1. Reference values for maximum permissible initial and minimum permissible operating viscosities for various types of pump

Type of pump	Maximum permissible initial viscosity, mm^2/s	Minimum permissible operating viscosity, mm^2/s
Gear pumps		
Without hydraulic gap compensation		
	1000–2000	25
With hydraulic gap compensation		
	1000–2000	15
Rotary vane pumps	850	20*
Fixed vane pumps	850	25*
Radial and axial piston pumps		
With control plane or edges	500 – 850	10 – 15
With sprung-loaded valves	200 – 300	8 – 12

Viscosity–Temperature (V–T) Behavior (ISO 2909, DIN 51 563). The viscosity of virtually all liquids decreases with increasing temperature. The viscosity index (VI) is an empirical measure of the V-T behavior. Fluids having a large viscosity–temperature dependence are commonly referred to as 'low-viscosity index' fluids. Those having a small viscosity–temperature dependence are known as high-viscosity index fluids. In the case of the normal demands on hydraulic oils a VI of ca. 100 is generally used. For sensitive control systems a VI of 100 is not adequate. Examples are hydraulic motors in machine tools or military equipment; and "mobile hydraulics" in aircraft, railways, motor vehicles, and construction equipment. In such cases *high VI hydraulic fluids* (HVI) are used. They are composed of mineral oils with polymer additives as VI improvers, (e.g., polymethacrylates) or occasionally synthetic oils.

Viscosity–Pressure (V–p) Behavior. At constant temperature the viscosity of hydraulic fluids increases exponentially with increasing pressure. The viscosity–pressure coefficient is larger at low temperatures than at high temperatures and the viscosity–pressure dependence is more pronounced in high-viscosity oils than in low-viscosity oils. Thus, the viscosity–pressure curve for a polyoxyalkylene–water mixture is significantly flatter than for mineral oils [3]. There are no standardized methods for determining the pressure dependence of viscosity [4].

Viscosity–Temperature–Pressure Behavior. The opposing effects on viscosity caused by an increase in pressure and temperature to some extent compensate one another. A three-dimensional form of diagram is used to show the combined effect [5].

Density–Temperature–Pressure Behavior (ISO 91 Pt. 1, DIN 51 757). Pressure losses in pipes are directly proportional to the density of the operating fluid. The density decreases with increasing temperature and increases with increasing pressure. For mineral oils the *volumetric expansion coefficient* is ca. 70×10^{-5} °C^{-1}. Up to ca. 300 bar the average *compressibility* of air-free mineral oils is 70×10^{-6} bar^{-1} [1]. At increased pressure liquids have a greater resistance to reduction in volume, i.e., with increasing pressure the fluids have a "harder" action [6].

Air-Dissolving and Air-Separating Ability (ASTM D 2779, ASTM D 3427, ASTM D 3827, DIN 51 381, IP 313). Under normal conditions hydraulic fluids can dissolve significant quantities of air: mineral oils and phosphate esters dissolve 7–9 vol %; aqueous solutions up to 5 vol % [7]. A certain time is required to dissolve air bubbles at increased pressure: ca. 10 s for 10 mm^2/s mineral oils at 2.0 MPa and 40 °C, and ca. 60 s for 40 mm^2/s oils [8]. Dispersions of air bubbles in hydraulic oils are undesirable because they increase the compressibility, promote aging of the fluid, reduce the thermal conductivity and can lead to cavitation damage in the pumps [9]. The ability of a fluid to expel dispersed air is known as its air release property. Under the conditions of the test standard DIN 51 381 the time is determined in which a dispersed quantity of air is released from the oil down to a residual air content of 0.2 vol %. The air release approaches this value asymptotically [10]. There is still no well-founded experience available to determine the quantity of dispersed air which leads to serious damage in hydraulic systems.

Foaming Behavior (ASTM D 892). If stable air bubbles build up on the surface of a fluid and are enclosed in extremely thin films of oil then unwanted surface foam has formed. This can lead to overflowing of the hydraulic oil container, or in the worst cases, to foam instead of oil being drawn into the system. Defoamers containing silicone oil remedy the situation but have an adverse effect on the air release properties [1]. More recent formulations contain defoamers based on polydimethylsiloxanes. The laboratory test as specified in ASTM D 892 in which a foam is produced in the liquid with the aid of a spherical gas diffuser stone has only limited practical value.

Behavior in the Mixed-Friction Zone (ASTM D 2271, ASTM D 2783, ASTM D 2882, DIN 51 350 Pt. 2, DIN 51 354 Pt. 2, Normungsaufgabe 0 051 589 Pt. 2). In a hydraulic system friction parts move (at least for short periods) under conditions of boundary friction. In this situation the normal force components which are not hydrodynamically supported cause partial elastic and plastic deformation of the sliding components. Physically-acting *antiwear additives* based on phosphorus, compounds and fatty acids and their derivatives, reduce wear and friction.

The FZG gear rig is used to determine the maximum load-carrying ability with stepwise increase in loading. The method is suitable for assessing the load-carrying ability of hydraulic oils and experience has shown that it gives very good agreement with axial piston pumps.

The Vickers 35VQ25 vane pump provides a practical test of the antiwear properties of hydraulic oils, the loss in mass of the vane and ring being measured before and after test run.

Seal Compatibility (ISO 1817, ISO 6072, ASTM D 3604, DIN 53 538 Pt. 1, Pt. 2 and Pt. 3, CETOP (Comité Européen des Transmissions Oléohydrauliques et Pneumatiques) RP 81H. There must be very little swelling, hardening, shrinking or softening of rubber-elastic sealing materials in contact with the hydraulic fluid. Apart from the type of sealing material and the operating conditions, the basic oil and additives (and any decomposition

products) have the greatest effect on the interaction between the sealing material and the hydraulic oil [12]. Due to the difficulty of applying static storage tests to dynamic operating processes there is as yet no satisfactory means of predicting seal compatibility. In the ISO 1817 method, disks of the sealing material are stored with all sides exposed in the hydraulic oil. Appropriate standard reference elastomers are specified in ISO 6072, DIN 53 538 Pt. 1 to Pt. 3, and in the CETOP R 81H regulations [13]. At the end of the test period the changes in mass, volume, hardness and tensile strength of the test piece are determined.

Fire-Resistance (ASTM D 3119, ASTM E 659, DIN 51 719, FTM 791b-6053) Fire-resistant hydraulic fluids are used in cases where the escaping fluid can come into contact with the sources of ignition. The method specified in DIN 51 794 is used for mineral oil products. Here a small sample quantity is placed in a heated, open Erlenmeyer flask. The lowest value at which combustion occurs in a series of tests is recorded. In the United States manifold ignition test (FTM 791b-6053) the fluid is dropped onto a hot discharge pipe and the temperature of combustion is recorded. The *mining industry* determines the flammability of a fluid sprayed under pressure [14]. There are differences between the continental and British tests [15]. In both cases the flame propagation is measured in a mixture of pulverized coal and fluid. The American industry applies two types of test: The United States Mining Safety and Health Administration Schedule 30 and the Factory Mutual-Less Hazardless Hydraulic Fluid Approval Standard 6930. Each test consists of two sets of tests with the pure fluid. The term “fire-resistant” has not yet been defined; it is not identical with “non-combustible.”

Cooling Ability. In a typical hydraulic system the proportion of power which is converted into heat is 15–25 % [16]. The specific heat and thermal conductivity of the hydraulic fluid used is necessary to calculate the power loss, dimensions of heat exchangers and amount of preheating (see Table 2).

Table 2. Calorific data of hydraulic fluids

	ISO/DIS	Water	Mineral oil 6074	HFA* 6071	HFB* 6071	HFC* 6071	HFD* 6071
Specific heat	W kg^{-1} K^{-1}	1.163	0.523	1.163	0.93	0.92	0.34
Thermal conductivity	W m^{-1} K^{-1}	0.628	0.129	0.628	0.523	0.309	0.114

Corrosion Protection (ASTM D 4636, DIN 51 585, FTM 7916–5308, SAE J 1703). The simultaneous action of oxygen and water on a metal surface forms galvanic cells which can lead to damage of the surface [1].

In the method as specified in DIN 51 585 a steel rod is immersed in a mixture of oil and water which is stirred for 24 h at 60 °C. However, this *dynamic test* is not sufficient for identifying the degree of corrosion protection when plants are shut down and parts covered with a thin film of oil are permanently in contact with moist air.

So-called immersion tests in which various metals and metal pairs are immersed in the fluid are used as *static tests*. Examples are magnesium, aluminum, cadmium, steel and copper as specified in FTM 791b-5308; or tin plate, steel, aluminum, cast iron, brass, and copper as specified in SAE J 1703.

System Cleanliness. The addition of dispersants as cleaning agents has the effect of dispersing solid foreign matter and suspending small quantities of water in the hydraulic oil. Any excess of water is rapidly precipitated. Suitable additives can significantly prolong the service life of hydraulic oils [17]. To test the cleaning ability solid precipitates are formed by hydrolyzing suitable additives, particularly zinc dialkyldithiophosphates. Subsequent filter tests are then used to test the filterability of the particles held in suspension [18]. Hydraulic oils with these properties are generally designated as “HLPD” without it being described more precisely in a specification standard. Further tests on hydraulic fluids comprise the determination of the hydrolytic stability (ASTM D 2619), the thermal stability (ASTM D 2160), and the deposition tendencies (ASTM D 3711). The standard practice ASTM D 4174 is intended to aid operators towards maintaining clean petroleum fluid hydraulic systems.

[Top of Page]

4. Additives to Hydraulic Fluids

Lubricating additives (⟶ Lubricants and Lubrication), are highly important components of modern hydraulic fluids. Whereas some properties of hydraulic oils cannot in practice be influenced by additives (e.g., *V–p* behavior), improvements of other properties are possible (e.g., anticorrosion, foaming) or the additives even give the hydraulic oils properties which are completely lacking in the base fluid (e.g., antiwear behavior). Additives in hydraulic fluids can have three different functions: (1) protection of the metal surface, (2) protection of the pressurized fluid, and (3) increasing the efficiency [19]. The most important additives for hydraulic fluids are listed in Table 3.

Table 3. Breakdown of additives for hydraulic fluids

Additive type	Function	Type of material	Mode of operation
Protection of the metal surface			
EP additives	prevention of surface damage under severe loading	organic compounds with sulfur, phosphorus or chlorine	chemical reactions with metal surface; formation of boundary layers
Antiwear additives	prevention of surface damage under light loading	fatty acids and derivatives	chemisorption at the metal surface; formation of boundary layers
Corrosion inhibitors	prevention of ingress of oxygen and water	fatty acids, sulfonates, salts of fatty acids	formation of coating layers, impermeable to water or air
Protection of the hydraulic fluid			
Oxidation inhibitors	inhibition of the reaction between air and fluid	phenols, amines, sulfides	interruption of the oxidation radical chain mechanism
Defoamers	prevention of the formation of stable foam	silicone oils	destruction of the oil skin surrounding the air bubbles
Increasing the efficiency			
VI improvers	reduction in the temperature dependence of viscosity	polyolefins, polymethacrylates, polyalkylstyrenes	greater increase in viscosity at higher rather than at lower temperatures
Pour-point depressants	lowering of the pour point	polymethacrylates, condensation products	coating of paraffin crystals and prevention of their growth
Demulsifiers	separation of oil and water	ionogenic and nonionogenic polar compounds	interaction with the oil–water interface
Dispersants	prevention of deposits	sulfonates, amides, surfactants	peptization

Additives which are suited to the type of fluid concerned are used alone or in multiple combinations to fulfil given specifications. Other additives are used for special purposes, e.g., emulsifiers, thickeners, friction modifiers.

[Top of Page]

5. Types of Hydraulic Fluids

Basically, any liquid is suitable for transmitting pressure. Water is therefore the cheapest medium and is universally available. Pure water, however, is too corrosive, can be used only between 0 and 100 °C, and does not provide sufficient wear protection for moving parts because of its low viscosity. These systems also require a significant amount of maintenance (e.g., treatment with biocides). Thus, the majority of hydraulic oils today have mineral oils as the base fluid. The required properties are achieved by choosing suitable mineral oil fractions and adding selected additives. Other base liquids are used for special power transmission duties.

5.1. Mineral Oils for Hydrostatic Machines

Hydrostatic machines, e.g., machine tools, presses, and construction machinery, normally require kinematic viscosities between 32 and 100 mm^2/s at 40 °C (ISO viscosity grades, VG, 32–100). Control plants, tippers and small loaders also use hydraulic fluids with lower viscosities of 10 to 22 mm^2/s at 40 °C (ISO-VG 10 to 22). Mineral-oil-based hydraulic oils for hydrostatic machines are therefore available in grades ISO VG 10 to 100 [1], [20].

Depending on the requirements resulting from the structural specification of the hydraulic machine and on the operating conditions there are five different qualities of hydraulic fluids available in the range ISO VG 10–100 (see Table 4).

Table 4. Mineral-oil-based hydraulic oils

German designation	International designation	Properties	Additives	Application	Quality specifications
Hydraulic oil H	HH	not oxidation inhibited	none	for lightly loaded systems	DIN 51 517 Pt. 1
Hydraulic oil HL	HL	oxidation-inhibited rust-preventing	ca. 0.5 %	for moderately loaded systems	DIN 51 524 Pt. 1 ISO 6074 SEB 181 222 VDMA 24 318
Hydraulic oil HLP	HM	oxidation-inhibited rust-preventing	ca. 1.0 %	for high pressure systems	DIN 51 524 Pt. 2 ISO 6074 SEB 181 222 VDMA 24 318
Hydraulic oil HVLP	HV	as for HM, shallow VT curve, high VI	ca. 8 %	for high pressure plants with fluctuating temperatures	DIN 51 524 Pt. 3 ISO 6074
Hydraulic oil HLPD		as for HM, dirt-suspending, limited water-compatibility, foam controlled	ca. 2.0 %	for systems with ingress of water	DIN 51 524 Pt. 4 SEB 181 222 VDMA 24 31

The characteristic data for the specification standards as specified in DIN 51 517 Pt. 1, DIN 51 524 Pt. 1, DIN 51 524 Pt. 2, DIN 51 524 Pt. 3, SEB (Stahl-Eisen-Betriebsblätter) 181 222 and CETOP RP 91H for ISO-VG 46 are listed in Table 5. The NATO Code H-540 (TL 9150–0035) designates a hydraulic oil for an operating range from – 30 to + 90 °C with a base oil comprising a mixture of refined mineral oil and polyalphaolefins.

Table 5. Selected quality data for mineral-oil-based ISO VG 46 hydraulic oils

Property	Test method	Units	DIN 51 517 Pt. 1	DIN 51 524 Pt. 1	DIN 51 524 Pt. 2	SEB 181 222	CETOP RP 91H	DIN 51 524 Pt. 3
Classification	ISO/DIS 6074		HH	HL	HM	HM	HV	HV
Viscosity at 0 °C	DIN 51 562	mm^2/s		<780	<780	<700		<420

[c] Report.

5.2. Mineral Oils for Hydrokinetic Systems

In hydrokinetic systems (e.g., hydrodynamic couplings; turbo gears systems with power transmission oils; automatic gear systems in vehicles) refined mineral oils are used which have a low viscosity and low viscosity-temperature dependence in order to achieve a high efficiency through low flow losses. The viscosity should not exceed 40 mm^2/s at 40 °C and the VI may reach 150.

Good oxidation protection is required for oils in *hydrodynamic couplings* and converters as the slip can cause severe heating. Higher demands are placed on *power transmission oils*. These are (1) corrosion protection in the oil and vapor phases; (2) good air release properties; (3) low tendency to foam; and (4) high load-bearing ability for lubrication of the heavily-loaded toothed gear systems. The oils used for *lubricating* and *controlling* motor vehicles with automatic transmission systems are called *automatic transmission fluids* (ATF). Because of their many functions and the high demands placed on them ATFs contain more additives (friction modifiers, oxidation inhibitors, and antiwear additives). The two commercially available types of fluid differ principally in their coefficients of friction: the coefficient of friction of Dexron II-ATF from General Motors (specification GM 3032M or GM 6137M) is considerably lower when static than when in motion; Ford type F fluids (specification M2C-33F or M2C-9007A) follow the natural friction pattern of mineral oils with high static and lower kinetic coefficients of friction [21].

5.3. Mineral Oils as Multipurpose Oils

Universal tractor transmission oils (UTTOs) are used for hydraulic performance in tractor applications, where manufacturers will have their own specifications that need to be met. Low viscosity motor oils, SAE 10W or SAE 5W, are also used as the hydraulic medium for the steering hydraulics in motor vehicles [22].

Since the end of the 1970s universal oils have been on the market for lubricating the motor and for the entire power transmission system of tractors. They are known as STOU (super tractor oil universal). The STOUs correspond principally to the viscosity grades SAE 10W-30, 10W-40, or 15W-30, fulfil the requirements of API CF-4/CE/SF and satisfy the gear oil specification MIL-L-2105 (API GL4) and industrial specification DIN 51524 Part 3 [23]. Tractor manufacturers require that their own specifications should be met for wet hydraulic braking systems, couplings and hydraulic equipment [24]. Dual-purpose, water containing metal-working and hydraulic fluids are on the market (MH-fluids) [25].

5.4. Aircraft and Marine Hydraulic Fluids

In aircraft, the ailerons, vertical rudder, elevators, tailplane, spoilers, landing flaps, equipment for lowering the landing gear, steering and braking equipment are actuated by hydrostatic hydraulic systems. The particular requirements for hydraulic oils used in aircraft are: (1) extremely low wear in pumps and valves, (2) very good low-temperature behavior (down to – 54 °C), and (3) very low tendency to fire propagation [26]. At present there are four groups of aviation hydraulic oils in use: (1) mineral oils (specification MIL-H-5606, NATO Code H-515); (2) polyalphaolefin oils (specification MIL-H-83 282) [27]; (3) oils made from alkyl or aryl phosphoric acid esters (Boeing company specification BMS 3-11E); and (4) the silicate ester-based oils (used in Concorde supersonic aircraft). Novel silahydrocarbon-based fluids have been under test in the 1980s [28], [29].

A comparison of selected requirements for hydraulic oils for aircraft is given in Table 6. Chlorofluoroalkane oils, which are substantially more fire-resistant than previous hydraulic oils, are under trial (Table 7) [26]. Hydraulic oils used in marine applications must have outstanding corrosion protection properties, e.g., marine hydraulic oil, NATO Code H-570. Consequently they must pass the corrosion test according to ASTM D 665 with sea water.

Table 6. Selected requirements for aviation hydraulic oils

	MIL-H-5 606 G	MIL-H-83 282 D
Base oil	mineral oil	polyalphaolefins
Viscosity (– 54 °C) mm^2/s	<2500	*
Viscosity (– 40 °C) mm^2/s	<600	<2200
Viscosity (+ 100 °C) mm^2/s	>4.9	>3.45
Pour point, °C	<–60	<–55
Elastomer swelling, %	19–30	18–30
Wear scar in the four-ball test, mm	<1.0	< 0.65

Sludge volume, mL	<65	<65

* Not required.

Table 7. Ignition and combustion properties of aviation hydraulic oils

	Flash point, °C (COC)	Fire point °C	Spontaneous ignition temperature, °C	Ignition on hot surface, °C
Test method (ASTM)	D 92	D 2155	E 659	D 1241
Type of aviation hydraulic oil				
Mineral oil (MIL-H-5606)	>82	113	232	593
Polyalphaolefin (MIL-H-83 282)	>204	250	344	538

Silicate ester	200	250	380	
Chlorofluoroalkane	none	none	643	none

5.5. Fire-Resistant Hydraulic Fluids

The flammability of mineral oils and their subsequent combustion can be dangerous in many industrial plants. Examples of this type of plant are: hydraulic systems in underground mining, in blast furnaces, in foundries, for welding equipment, and for injection molding machines. Fire-retardant hydraulic fluids have been developed for these applications since 1960 [30]. In accordance with a recommendation in the 7th Luxembourg Report [14] the fire-resistant hydraulic fluids (HF) were divided into four classes as specified in ISO/DIS 6071 (see Table 8).

Table 8. Types of fire-resistant industrial hydraulic fluids

Designation	Description	Water content, %	Viscosity at 40 °C, mm^2/s	Range of application, °C
HFA	oil-in-water emulsion	> 80	ca. 1	+ 5–+ 55
HFAE	HFA with 80 % water [a, d]			
HFAS	solution of chemical substances [a, e]			
HFB	water-in-oil emulsion	> 40	46–100	+ 5–+ 60
HFC	aqueous polymer solutions	> 35	22–100	– 20–+ 60
HFD	water-free synthetic liquids		15–100	– 20–+ 150
HFDR	phosphoric acid ester [c]			
HFDS	chlorinated hydrocarbons [c]			
HFDT	mixtures of HFDR and HFDS [c]			
HFDU	other compositions [c, f]			

[a] ISO 6743/4.
[b] ISO/DIS 6071.
[c] ISO 6743/4; ISO/DIS 6071; VDMA 24 317; CETOP RP 77H.
[d] DIN 24 320.
[e] Mainly polyalkylen glycols.
[f] Not specified.

HFA fluids (pressurized water) with water contents of 95–98 % are the only fire-resistant hydraulic fluids that are effectively incombustible. Due to the low viscosity of the fluid (practically that of water) valves with gap-sealing cannot be used at high pressures and the antiwear properties are very poor [31], [32]. Attempts are being made to overcome these disadvantages by the use of microemulsions [33] (colloidal oil droplets of 1–5 µm in diameter) and by the addition of water thickeners (raising the viscosity to 150 mm^2/s at 40 °C) [34], [35].

HFB fluids are in widespread use in the United Kingdom and the United States [36]. However, they do not play any role in.

The majority of *HFC fluids* are aqueous *polyoxyalkylene solutions* (⟶ Polyoxyalkylenes) containing about 10 % additives. Their antiwear properties are unsatisfactory, especially with roller bearings.

Phosphate ester based oils (*HFDR* fluids) have good fire resistance and excellent antiwear/anticorrosion properties. However they are expensive and also require careful maintenance—for example, to prevent water contamination and in turn build up of acidic components.

Polyol ester based fluids (*HFDU*) also claim similar performance benefits and are more cost-effective. Although they are not considered to be as fire resistant as phosphate ester based fluids, they are more commonly used in many industrial applications where a synthetic fluid is preferred.

5.6. Brake Fluids

Specifications. Brake fluids are specified according to SAE standards, of which SAE J1703 is the best known (see Table 9). Equally well known are the FMVSS (Federal Motor Vehicle Safety Standard) specifications issued by the United States Department of Transportation (DOT). These standards are recognized worldwide by vehicle manufacturers. The ISO standard 4925 corresponds with these specifications. The reader is referred to SAE Specification J1709 for a description and classification of the different types of brake fluid.

Table 9. Specifications for brake fluids with the required minimum boiling point

Specification	Designation	Minimum boiling point, °C

SAE J 1703	motor brake fluid	205
SAE J 1704	borate ester based brake fluid	230
FMVSS 116 DOT 3	motor vehicle brake fluid	205
FMVSS 116 DOT 4	motor vehicle brake fluid (borate)	230
FMVSS 116 DOT 5.1	motor vehicle brake fluid (borate)	260
FMVSS 116 DOT 5	silicone based brake fluid	260
ISO 4925	motor vehicle brake fluid	205

Glycols as Brake Fluids. In motor vehicles the pressure developed in a master brake cylinder is transmitted by the brake fluid to the wheel brakes where a friction surface is pressed against a rotating drum or disk. The main requirements of such fluids are a high boiling point and compatibility with the brake tubing and seals. In addition to glycols of the general formula HO —R —OH, use is also made of glycol ethers (HO —R —O —R′). These materials are hygroscopic. Components are added to enhance lubricity, antiwear and antioxidation properties and for corrosion inhibition. Brake fluids are classified by three main physical characteristics: (a) dry equilibrium boiling point as defined by specification (boiling point), (b) wet equilibrium boiling point—relating to simulated years of (hygroscopic) fluid in service, and (c) kinematic viscosity at – 40 °C.

Newer Brake Fluid Types.
Borate Esters. Developments in the 1970s led to borate esters (glycol ether borates) which have higher boiling points and higher performance characteristics than glycol ethers, but are still hygroscopic.

Silicon Esters. In the late 1990s, silicon esters, (glycol ether silicates) with very high performance were developed. These fluids are expensive, and used mainly in racing applications.

Silicone Oils. These are used in some applications but are expensive and more compressible than current glycol ether derivatives.

Mineral Oils. In some specific vehicle applications, specialized mineral oil based brake fluids are used. These are not compatible with glycol ether-based fluids and must never be mixed. ISO specification 7308 relates to these fluids.

5.7. Environmentally-Friendly Hydraulic Fluids (⟶ Chlorinated Hydrocarbons – Chlorinated Biphenyls)

Environmentally-friendly hydraulic fluids are slowly gaining popularity with growing environmental awareness and, in particular, increasing legislation stipulating use of ‘bio’ products in sensitive outdoor applications. Natural oil-based products (HETG type) are typically based on rapeseed oils and have good biodegradability and lubricity. However, they have poor oxidative stability (which can lead to deposits in severe applications), reduced service life and variable low temperature properties. Products based on synthetic esters (HEES type) also show good biodegradability, improved oxidative stability, good low temperature properties and longer service life. However, cost is an issue as they are six to ten times as expensive as natural oil-based products. Compatibility with seal materials is a concern for both types of fluid.

[Top of Page]

6. Various Aspects of the Use of Hydraulic Fluids

Filtration Problems. Impurities in hydraulic systems lead to premature wear of the parts and to unforeseen malfunctions. Continuous cleaning of the operating fluid (usually with filters or electrostatic liquid cleaners [40]) is therefore necessary. The choice of filter is governed by the operating conditions and requirements. The filter mesh size, the dirt-retaining capacity of the filter, the permissible pressure drop and the operating viscosity of the fluid [41] are the most important parameters to be considered. The *filter fineness* is required to achieve a given degree of purity [42], [43]. This depends mainly on the hydraulic system and its gap widths [44], [45].

The *cleanliness of a liquid* can be given by two numbers as specified in ISO/DIS 4406: the first number refers to the number of particles per milliliter with a diameter of >5 µm and the second figure to particles above 15 µm diameter; e.g., 15/12 = 160–320 particles per milliliter of diameter greater than 5 µm of which 20–40 particles per milliliter have a diameter greater than 15 µm. The relation between number of particles and the corresponding code is given in ISO/DIS 4406. The *efficiency of a filter* is expressed by the β-value [46]. This is determined in the ISO 4572 Multipass Test as the quotient of the number of particles before and after the filtration. Table 10 shows the purity classifications for the fluid and the β-values for the filter for selected areas of application [47].

Table 10. Areas of application, purity classification of the fluids and β-values of the filter

Area of application	Purity classification ISO/DIS 4406	β-Value
Machine tools	8/4–14/10	75 *
Hydraulic presses	8/4–14/10	75
Plastic injection machines	9/5–13/9	75
Construction machines	10/4–12/10	75
Excavators	13/6–20/13	75
Control hydraulics	10/6–13/8	75
Mobile hydraulics	13/6–18/13	75
Hydrostatic drives	13/7–17/10	75

* 75 Corresponds to a separating efficiency of 98.67 %.

Change of Type of Hydraulic Oil. If a change is to be made from a mineral oil to an aqueous fluid or a synthetic oil, or the reverse, a number of points must be taken into account. The questions regarding the disposal of the used fluid, material, tubing, paint, sliding bearings and filters, tolerances, auxiliary cleaning aids, etc. are listed in the VDMA (Verband deutscher Maschinenbau-Anstalten) 24 314 guidelines. The cost of equipment alterations may also need to be taken into account (for example, if switching from a mineral oil to HFA type fluid). (see Table 11) [48].

Table 11. Cost comparison of hydraulic equipment for a transfer line

	Operation with mineral oil	Operation with HFA fluid
Plant costs, %	100	187

Energy costs, % 100	190

Condition Monitoring. Where fairly large quantities of fluid are involved, the serviceability of a working fluid in operation is determined by laboratory testing of used oil samples, sometimes in combination with wear metals analysis [49]. There are standardized guidelines (ISO 4021; CETOP RP 91H) and practical advice for taking representative samples [50], [51]. In addition to systematic laboratory tests [1], [52] it is sometimes also advantageous to use rapid analysis kits [53], [54].

Toxicology and Occupational Health. Mineral oils are relatively nontoxic substances. Their proper use is not associated with any increased health risk if the usual working precautions are observed for avoiding skin contact or inhalation of vapors and mists [1].

Biocides, which often operate by releasing formaldehyde, are used with the *HFA* and *HFB* hydraulic fluids to combat infection by microorganisms. The concentration of biocide is generally so low that neither the MAK value (0.5 ppm in 2002) nor the TLV (1.5 mg/m^3) for formaldehyde is reached. However, specialist advice should be sought if there are any doubts regarding health issues if using these fluids.

The *HFDS fluids* were composed of polychlorinated biphenyls (PCBs, trademarks: Avoclor, Askarel, Clophen, Pyroclor, etc.). It is no longer permissible to manufacture and use PCBs because of their persistent, and presumed carcinogenic, properties.

The main product group of the *HFDR fluids* are the triarylphosphates which have a series of isomers showing pronounced toxic properties. However, starting from 3,4- and 3,5-xylenols it is possible to prepare products which have met the strict toxicity requirements of the 7th Luxembourg Report [14].

1. Introduction

The existence of hydrazine [*302-01-2*], $H_2N{-}NH_2$, M_r 32.05, was predicted by Emil Fischer in 1875 [12], and it was first isolated in 1887 by Curtius [13]. Anhydrous hydrazine was isolated in 1893 by de Bruyn [14]. The first commercial production process was invented by Raschig in 1907 [15]; it is still in use in Japan, Russia, China, and Korea. Following the rapid increase in the use of hydrazine and its derivatives as blowing agents for plastic foams came other industrial applications: boiler water treatment, polymerization initiators, pesticides, pharmaceuticals, photographic chemicals, and dyes.

A century after its discovery, hydrazine is still difficult to synthesize, mainly for thermodynamic reasons. Most hydrazine is produced by variations of the Raschig process, the oxidation of ammonia by hypochlorite. However, the new plants built since 1980 are based on the PCUK process, which uses hydrogen peroxide as oxidant.

Most hydrazine is sold as an aqueous solution of up to 64 % concentration, corresponding to hydrazine hydrate [*7803-57-8*], $N_2H_4 \cdot H_2O$.

2. Physical Properties

Hydrazine is a colorless liquid with an ammoniacal odor. It is miscible with water in all proportions, and its aqueous solutions are highly alkaline. Some physical properties of hydrazine and its aqueous solutions are listed in Table 1. Certain physical properties of the aqueous solutions, e.g., viscosity and density, display a maximum value at the 64 % composition (corresponding to the monohydrate), suggesting that the hydrate, $N_2H_4 \cdot H_2O$, exists in both the solid and the liquid phase (Figure 1). Hydrazine forms an azeotrope (*bp* 120.5 °C) with water, containing 58.5 mol % hydrazine.

Hydrazine is an endothermic compound with a heat of formation of +50.6 kJ/mol. The explosion limits in air are 4.7 – 100 %. The upper value indicates that anhydrous hydrazine is self-explosive. Dilution with an inert gas such as nitrogen or water significantly reduces the flammable domain by raising the lower explosion limit [21]. Hydrazine hydrate (30.9 vol% hydrazine) can therefore be handled without danger at atmospheric pressure at 120 °C in the absence of air.

3. Chemical Properties

The chemical properties of hydrazine are strongly influenced by the following characteristics: the compound is endothermic, a base, and a reducing agent.

Thermal Decomposition. A relatively high temperature (250 °C) is required, in the absence of catalysts, for significant decomposition to occur [17, 22]:

$$3\,N_2H_4 \longrightarrow N_2 + 4\,NH_3 \quad \Delta H = -157\ \text{kJ/mol}$$
$$N_2H_4 \longrightarrow N_2 + 2\,H_2 \quad \Delta H = -95.4\ \text{kJ/mol}$$
$$N_2H_4 + H_2 \longrightarrow 2\,NH_3 \quad \Delta H = -187.8\ \text{kJ/mol}$$

The decomposition temperature is lowered by several catalysts (e.g., copper, cobalt, molybdenum, and their oxides) [17]. Hence, hydrazine should be handled carefully.

Acid – Base Reactions. Hydrazine is a weak base that reacts with water:

$$N_2H_4 + H_2O \longrightarrow N_2H_5^+ + OH^- \quad K_b = 8.5 \times 10^{-7}\ (25\,°C)$$
$$N_2H_5^+ + H_2O \longrightarrow N_2H_6^{2+} + OH^- \quad K_b = 8.9 \times 10^{-16}\ (25\,°C)$$

The cation $N_2H_6^{2+}$ occurs only in strongly acidic solutions or in the solid state [23].

Hydrazine forms salts with acids [17], some of which are explosive, e.g., the nitrate, perchlorate, and azide. Other salts, such as the hydrochloride, hydrobromide, or sulfate, are commercially available and can be handled in the same way as hydrazine hydrate.

Reducing Agent. Hydrazine is a strong reducing agent which reacts exothermically with oxygen:

$$N_2H_4 + O_2 \longrightarrow N_2 + 2\,H_2O \quad \Delta H = -621\ \text{kJ/mol}$$

Many of the uses of hydrazine are based on this reaction (see Chap. 9). Several metals catalyze the oxidation of hydrazine by air in alkaline solution. For this reason, copper and poly-

valent metals or their salts must be absent or deactivated when hydrazine solutions are distilled [24,25]. The oxides of cadmium, magnesium, zinc, and aluminum stabilize hydrazine solutions against aerial oxidation [26,27].

In acid solution hydrazine reacts with halogens [28,29]:

$$N_2H_4 + 2\,X_2 \longrightarrow N_2 + 4\,HX$$

where X = F, Cl, Br, I

These reactions are used to determine N_2H_4 (with iodine), to purify crude hydrogen halides, and to remove traces of halogens in wastewater. Traces of hydrazine may be removed by the same procedure. For waste or spills it is more convenient to use sodium hypochlorite:

$$N_2H_4 + 2\,NaClO \longrightarrow N_2 + 2\,NaCl + 2\,H_2O$$

or hydrogen peroxide in the presence of iron(III) or copper(II) salts:

$$N_2H_4 + 2\,H_2O_2 \longrightarrow N_2 + 4\,H_2O$$

Various metal ions or oxides, such as those of copper, silver, gold, mercury, nickel, and platinum, can also be reduced to pulverulent metals by hydrazine [30,31].

Ketones and aldehydes are reduced by hydrazine (the Wolff – Kishner reaction) [32]:

In the presence of a hydrogenation catalyst, such as Raney nickel, aromatic nitro compounds are reduced to the corresponding amines [33]:

In the presence of hydrogen peroxide, hydrazine is oxidized to diimide [*3618-05-1*], which reduces acetylenes to *cis*-alkenes:

$$N_2H_4 + H_2O_2 \longrightarrow NH{=}NH + 2\,H_2O$$

and hydrogenates residual double bonds in acrylonitrile – butadiene rubber [34].

Diamine Reactions. Hydrazine is widely used in the synthesis and production of numerous open-chain and heterocyclic nitrogen compounds, including hydrazo and azo compounds, pyrazoles, triazoles, urazoles, tetrazoles, pyridazines, and triazines [31].

4. Production

Availability of raw materials and production costs rule out most of the possible routes to hydrazine; nitrogen and ammonia are the only obvious starting materials for a reasonably direct process.

Consideration of the variation of standard free energy ΔF°(g) (298 K) for the gaseous system H_2–N_2–NH_3–N_2H_4 (Fig. 2, see next page) indicates that the direct synthesis of hydrazine from nitrogen and hydrogen is energetically unfavorable. The free energy of formation is clearly much more favorable for production of ammonia.

Figure 2. Variation of standard free energy (298 K) in the gaseous system H_2 – N_2 – NH_3 – N_2H_4

The search for selective reduction of nitrogen has not yet found a practical or economic solution. Therefore, ammonia remains the only valuable nitrogen starting material for production of hydrazine.

Coupling of two molecules of NH_3 with coproduction of hydrogen also appears, on paper, to be an attractive process. Such a reaction is, however, endothermic and highly inefficient. For example, decomposition of ammonia by an electric discharge, photolysis, or radiolysis gives only low yields of hydrazine. An alternative method is to oxidize the hydrogen atoms removed from the ammonia:

$$2\,NH_3 \xrightarrow{[o]} N_2H_4 + H_2O$$

Only three oxidants are relevant to an industrial process: chlorine, oxygen, and hydrogen peroxide.

A further difficulty is that hydrazine, which is a much more powerful reducing agent than ammonia, may also react with the oxidizing agent.

Chlorine has been widely used in the *Raschig process*, which is still operated. To avoid further oxidation of hydrazine by chlorine, very dilute conditions have to be employed. Yields are no higher than 60 %.

The use of air or oxygen as a clean oxidizing agent is hardly feasible. This process, discovered in the 1950s by Meyer et al. [35] and later studied extensively by Hayashi [39] can only be applied to a few aromatic imines that lead to aromatic azines, from which hydrazine can only be obtained as the sulfate:

$$(C_6H_5)_2C{=}O + NH_3 \xrightarrow[400\,^\circ C]{ThO_2} (C_6H_5)_2C{=}NH + H_2O$$

$$2\,(C_6H_5)_2C{=}NH + \tfrac{1}{2}O_2 \xrightarrow[Py]{Cu(I)} (C_6H_5)_2C{=}N{-}N{=}C(C_6H_5)_2 + H_2O$$

The only modern method consists of obtaining hydrazine as a derivative from which it may be easily and efficiently released. Azines of low molecular mass are suitable for such a purpose [17, 31]:

$$N_2H_4 + 2\,R_2C{=}O \rightleftharpoons R_2C{=}N{-}N{=}CR_2 + 2\,H_2O$$

The azines of acetone and methyl ethyl ketone are easily hydrolyzed under pressure forming hydrazine and regenerating the ketone [36–38]. Bayer has considerably improved yields by introducing acetone into the Raschig process.

In the 1970s, PCUK, (now Atochem) developed a new, efficient, and clean process based on the oxidation of ammonia by hydrogen peroxide in the presence of a ketone. Most hydrazine is now produced by the *ketazine process*, with oxidation of ammonia by chlorine or hydrogen peroxide.

4.1. Raschig Process

In the Raschig process [14, 40–42] sodium hypochlorite (obtained by reaction of chlorine with sodium hydroxide) is used to oxidize ammonia.

Two steps are involved in the oxidation (Fig. 3). In the first, carried out at ca. 5 °C, chloramine [*10599-90-3*] is formed by a fast reaction:

$$NaClO + NH_3 \longrightarrow NH_2Cl + NaOH$$

Figure 3. Raschig process for the production of hydrazine
a) Chloramine reactor; b), c) Hydrazine reactors; d) Ammonia evaporator; e) Hydrazine – sodium chloride separator; f) Hydrazine hydrate concentrator

The reaction mixture is then mixed with a large molar excess of ammonia (40 : 1) and the slow reaction leading to hydrazine is carried out at 130 – 150 °C and 3.0 MPa:

$$NH_2Cl + NH_3 + NaOH \longrightarrow N_2H_4 + NaCl + H_2O$$

The kinetics and mechanism [43–46] and the influence of various parameters such as temperature, pressure, concentration, and molar ratios have been examined [31].

The most important side reactions are the following:

$$2\,NH_2Cl + NaClO + 2\,NaOH \longrightarrow N_2 + 3\,NaCl + 3\,H_2O$$
$$2\,NH_2Cl + N_2H_4 \longrightarrow N_2 + 2\,NH_4Cl$$

At the outlet of the reactor, the reaction liquor contains 1 % hydrazine hydrate and ca. 4 % sodium chloride; the pressure is reduced to atmospheric in a battery of evaporators. Ammonia is condensed, concentrated, and recycled. The liquor from the bottom of the stripping columns is freed from salt in a conventional forced–circulation salting evaporator. The distillate is then concentrated to 100 % hydrazine hydrate.

For such a process, dilute solutions and a very high ammonia/hypochlorite ratio are essential in order to obtain reasonable yields. Evaporation costs are therefore high even when steam savings are realized.

4.2. Olin Raschig Process

In the Olin Raschig process (Fig. 4), which is used by Olin to produce anhydrous hydrazine for aerospace applications, the production of sodium hypochlorite is carefully controlled. A low temperature is used to prevent decomposition and chlorate formation, and the excess of sodium hydroxide is kept at a low level.

The sodium hypochlorite solution is mixed with a threefold excess of ammonia at 5 °C to form chloramine, which is then rapidly added to a 30-fold molar excess of anhydrous ammonia under pressure (20 – 30 MPa) and heated to 130 °C [47–49].

The reaction liquor, containing 1 – 2 % hydrazine hydrate, is treated as in the conventional Raschig process to give hydrazine hydrate. Anhydrous hydrazine is obtained by removing the water by azeotropic distillation with aniline in a column at atmospheric pressure. Condensation of the vapor yields a two-layer distillate; the aqueous phase is removed and the aniline phase refluxed to the top of the column. Anhydrous hydrazine is recovered as a mixture with aniline, from which it is separated by distillation [50].

4.3. Urea Process

Urea may be used as a source of ammonia in the Raschig process [51, 52]. Although not currently used for the production of commercial hydrazine hydrate, this process has been operated commercially and it is described in [53]. Compared with the standard Raschig process, it was the most economical method for low production levels, but with the rapid growth in plant size it became obsolete.

However, since 1990, large quantities of hydrazodicarbonamide are produced in Asia, by using the crude reaction mixture of urea and sodium hypochlorite as the source of hydrazine (see page 10). Because this process involves extensive formation of byproducts and expensive effluent treatment, it is likely to become obsolete.

4.4. Bayer Ketazine Process

The Bayer process (Fig. 5) is a variation of the Raschig process and is based on the reaction of chloramine with ammonia in the presence of acetone at pH 12 – 14 [54, 55]:

Sodium hypochlorite, acetone, and a 20 % aqueous solution of ammonia (molar ratio 1: 2: 20, respectively) are fed simultaneously and continuously into a reactor at ca. 35 °C and 200 kPa. Excess ammonia is removed from the reaction mixture by stripping, quenched with water, and recycled to the reactor as an aqueous solution. The aqueous dimethyl ketazine solution, freed from ammonia but containing unconverted acetone, sodium chloride, and organic impurities, is fed into a distillation column where the dimethyl ketazine is recovered as an aqueous azeotrope (containing 55 % dimethyl ketazine; *bp* 95 °C at 101.3 kPa) at atmospheric pressure. The injection of acetone into the distillation column is claimed to prevent premature hydrolysis of the ketazine. The byproduct from the still is a solution of sodium chloride containing traces of hydrazine and organic compounds. The solution must be treated before disposal or recycling to electrolysis.

The dimethyl ketazine is then hydrolyzed in a distillation column under pressure (0.8 – 1.2 MPa), giving acetone, which is recycled to the reactor, and a 10 % aqueous solution of hydrazine. The latter is then concentrated to a hydrazine content of 64 %.

4.5. Fisons Process

This process, originally operated by Whiffen and Sons, was developed by Fisons and went on stream in the 1960s. It used methyl ethyl ketone instead of acetone to trap the hydrazine; the hydrolysis was carried out with sulfuric acid.

This process is no longer operated.

Figure 5. Bayer hydrazine process
a) Azine reactor; b) Ammonia stripping; c) Ammonia quenching; d) Azine distillation; e) Azine hydrolysis; f) Hydrazine hydrate concentration

4.6. Peroxide Process

The most recent hydrazine process, invented by PCUK, is operated by ATOFINA in France and by Mitsubishi Gas in Japan. Hydrogen peroxide is the oxidizing agent. The reaction is carried out in the presence of methyl ethyl ketone (MEK) at atmospheric pressure and 50 °C. The ratio of H_2O_2: MEK: NH_3 used is 1: 2: 4.

The hydrogen peroxide is activated by acetamide [*60-35-5*] and disodium hydrogen phosphate [*7558-79-4*] (ATOFINA) or by an arsenic compound (Mitsubishi Gas) [56]. The overall reaction results in formation of methyl ethyl ketazine [*5921-54-0*] in high yield [57] (Fig. 6):

Figure 6. Peroxide process
a) Azine reactor; b) Phase separator; c) Aqueous phase concentration; d) Azine purification; e) Azine hydrolysis; f) Hydrazine hydrate concentration

The mechanism requires the activation of ammonia and hydrogen peroxide as these two reactants, unlike ammonia and hypochlorite in the Bayer process, do not react together [58–62]. The reaction pathway involves the formation of an oxaziridine intermediate that is able to oxidize ammonia to a hydrazine derivative.

Since methyl ethyl ketazine is insoluble in the reaction mixture, it is easily separated by decantation; it is then purified by distillation. The purified ketazine is hydrolyzed under pressure (0.8 – 10 MPa) to give concentrated aqueous hydrazine and overhead methyl ethyl ketone, which is recycled [37].

The aqueous layer containing the activator is concentrated to remove water and recycled to the reactors after a purge of water-soluble impurities.

The peroxide process has many advantages compared with other processes: no salt byproduct, high yields, low energy consumption, low molar excess, no aqueous effluent treatment [63].

5. Environmental Protection

Hydrazine has a noxious effect on bacteria, algae, and aquatic wildlife; therefore, emission of hydrazine-containing wastewater is not permitted.

Wastewater and spills that contain hydrazine must be collected, analyzed, and treated (e.g., by oxidation with NaClO or H_2O_2). The ammonia content should also be examined because hydrazine may also decompose into ammonia.

6. Quality Specifications

Hydrazine is commercially available as anhydrous hydrazine, as an aqueous solution, and as solid dihydrazinium sulfate. Some typical specifications are summarized in Tables 3 and 4 (both see next page).

Table 3. Specifications of anhydrous hydrazine (monopropellant grade)

Component	Specification
Hydrazine, wt %	≥98.5
Water, wt %	≤1.0
Chloride, ppm	≤5.0
Iron, ppm	4
Aniline, wt %	≤0.5
Nonvolatile residue, wt %	≤0.005
Carbon dioxide, wt %	≤0.003
Carbon volatile, wt %	≤0.02
Density (25 °C), g/mL	1.008 – 1.002

Table 4. Specifications of hydrazine hydrate

Component	Specification
Hydrazine hydrate, wt %	>100±0.5
Hydrazine, wt %	>64±0.4
Ammonia, wt %	<0.1
Chloride, ppm	<1
Iron, ppm	<1
Nonvolatile residue, ppm	<20

Although most hydrazine hydrate is manufactured by the ketazine process, there are no specifications relating to organic impurities.

7. Analysis

Analytical determination of hydrazine in solutions or mixtures is based on its properties as a weak base and strong reducing agent, and on the formation of highly colored derivatives.

A large number of methods have been described for hydrazine derivatives [64]; in this chapter, only analytical methods for hydrazine and hydrazine hydrate will be discussed.

Hydrazine is a weak base ($pK_b = 6.07$) and, in the absence of other bases, can be easily titrated with acid with methyl purple as the indicator. In the absence of other reducing agents, hydrazine can be determined quantitatively by oxidation, most commonly with iodine [65]:

$$N_2H_4 + 2\,I_2 \longrightarrow N_2 + 4\,HI$$

To obtain a stable end point, the pH must be maintained near neutrality, usually by adding solid sodium bicarbonate or ammonium acetate as a buffer. Starch is used as an indicator.

Traces of hydrazine (as low as 1 ppb) can be detected with an iodide-selective electrode [66].

Dilute solutions of hydrazine can be determined by colorimetry. The best method (ASTM D 1385 – 78) involves converting the hydrazine into highly colored azines, such as those of aromatic aldehydes; *p*-dimethylaminobenzaldehyde is particularly suitable for this purpose.

8. Handling, Storage, and Transportation

Hydrazine is volatile and toxic (see Chap. 12) and must be handled with care. Observation of elementary safety rules allows hydrazine to be used with little risk. In the absence of decomposition catalysts, anhydrous hydrazine may be heated up to 250 °C without appreciable decomposition. Aqueous and anhydrous hydrazine can be stored for long periods without problems; clean storage vessels of suitable material are required, together with an inert gas blanket, e.g., nitrogen.

Hydrazine vapors do, however, present hazards in gas mixtures, as shown in Table 5. Working in the vapor phase requires operation below the lower explosion limit.

Table 5. Lower explosion limits of gaseous hydrazine mixtures

Gas mixture	Hydrazine, %	Temperature, °C	Pressure, kPa
Hydrazine	100	30	2
Hydrazine – air	54.7	95	100
Hydrazine – nitrogen	38	110	100
Hydrazine – water	38	100	30

Hydrazine can be stored in drums of 304 stainless steel at room temperature, but stainless steel 316 must be avoided because of its high content of molybdenum, which is an efficient catalyst for the decomposition of hydrazine. Cold-rolled steel is satisfactory for hydrazine concentrations below 10 %. Other materials convenient for storage of anhydrous hydrazine include aluminum, tantalum, and titanium. Polytetrafluoroethylene, polyethylene, and polypropylene are also suitable, but poly(vinyl chloride) is not recommended.

Hydrazine must generally be stored under conditions that preclude oxidants. Anhydrous hydrazine may cause ignition of wood, rags, paper, or other common organic material. Fires can be extinguished easily, however, as hydrazine is completely miscible with water. Contact with

carbon dioxide must also be prevented, as this gas reacts readily to give a hydrazinium carbazic acid salt, which is quite unstable. Storage in direct sunlight should also be avoided.

Hydrazine is easily adsorbed orally, percutaneously, and by inhalation. Proper protection must be provided. This includes well-aired premises, gloves, glasses, appropriate masks, and boots. Skin or eye contact must be treated by washing copiously with water; a physician must be consulted. Premises where hydrazine is handled must be equipped with continuously operated analytical devices to ensure that the concentration in air does not exceed 0.1 ppm in Europe and 0.01 ppm in the United States.

Anhydrous hydrazine and its aqueous solutions are subject to national and international regulations relating to the transportation of hazardous materials, e.g., for transportation by rail (RID) and by road (ADR) in Europe, and the international regulations for transportation by sea (IMCO code) and air (IATA).

Anhydrous hydrazine (UN no. 2029) and hydrazine hydrate (UN no. 2030) aree classified (Class 8) as flammable liquids and poisous. Dilute aqueous solutions of hydrazine hydrate belong only to the Class 6 but are still considered as corrosive and toxic.

9. Uses

Most hydrazine is sold as an aqueous solution. The only outlet for anhydrous hydrazine is as a rocket fuel or as a mono- or bipropellant for satellites and spacecraft.

About 80 – 90 % of hydrazine production is converted into organic derivatives. All other applications are based on its use as a reducing agent, as an energy-rich compound, or on its hydrogen storage capacity.

The most important uses of hydrazine and its derivatives are as polymerization initiators and blowing agents for foamed plastics, and for the production of pesticides. Other uses include: synthetic building block, pharmaceuticals, propellants, and airbags for cars.

Blowing Agents. Many hydrazine-based blowing agents are produced industrially; world hydrazine hydrate consumption in 1998 for this application amounted to 50 000 t/a. They are all hydrazo or azo derivatives; the latter are obtained by oxidation of the former with chlorine or hydrogen peroxide. Blowing agents decompose on heating into nitrogen and mixtures of other gases thereby producing a foaming action in polymers to form pores or cells (→ Foamed Plastics). Some commercially produced hydrazine-based blowing agents are listed in Table 6.

The decomposition temperature of blowing agents depends on the particle size, the pH, and the presence of salts of barium, cadmium, or zinc, which act as activating agents.

One of the earliest commercial blowing agents was azobis(isobutyronitrile) (AIBN), which is used as a porophore for sponge rubber products and PVC foams. It is also em-

Table 6. Some hydrazine-based blowing agents

Compound	CAS registry number	Structure	Decomposition temperature in air, °C	Gas yield, mL/g
Azobis(isobutyronitrile)	[*78-67-1*]		115	130
Azodicarbonamide	[*123-77-3*]		195 – 200	220
Benzenesulfonylhydrazide	[*80-17-1*]	$C_6H_5SO_2NHNH_2$	95	130
4-Methylbenzenesulfonylhydrazide	[*1576-35-8*]	p-$CH_3C_6H_4SO_2NHNH_2$	103	120
4,4′-Oxybis(benzenesulfonylhydrazide)	[*80-51-3*]	$O<-(>C_6H_4SO_2NHNH_2)_2$	150	125

ployed as a free radical source in the initiation of polymerization. Azobis(isobutyronitrile) is produced from acetone cyanohydrin [*75-86-5*] and hydrazine:

Oxidation to the azo compound is effected with chlorine [67, 68]:

Azodicarbonamide is readily produced from urea and hydrazine:

The intermediate hydrazodicarbonamide, which can also be produced directly in situ from urea and sodium hypochlorite [69], is oxidized either by chlorine or hydrogen peroxide in the presence of a catalytic amount of bromide ions in a strongly acidic medium:

Azodicarbonamide is, in terms of production volume, the most important blowing agent. Its success is due to the large volume of gas evolved (220 mL/g at STP). Decomposition at 190 °C yields mainly nitrogen (60 vol %) and carbon monoxide (35 vol %), as well as small amounts of ammonia and carbon dioxide. The solid residues are colorless, odorless, nonstaining, and do not support combustion.

The need for blowing agents with a higher decomposition temperature for the manufacture of new rubber or porous plastic materials led to the appearance of sulfonic acid hydrazides in the 1950s. In contrast to the inorganic blowing agents previously used (e.g., ammonium nitrite, ammonium bicarbonate, sodium bicarbonate) these sulfonic acid hydrazides are more easily dispersed, can be safely handled at a higher temperature, and give improved foam cell structure. They are also colorless, odorless, nonstaining, and the decomposition products are safe. The following explanation of decomposition has been proposed:

The sulfonic acid mono- and dihydrazides are produced from hydrazine hydrate and the appropriate sulfonic acid chloride:

The handling and technology of blowing agents have been reviewed [70, 71].

Air-Bags. Sodium azide [*26628-22-8*] is widely used as gas precursor in air-bag technology. One of the industrial processes for its manufacture starts from hydrazine and an alkyl nitrite [72].

An other hydrazine derivative is under development for the same application: 5-aminotetrazole [*4418-61-5*] obtained from aminoguanidine salts [73].

Free-Radical Polymerization Initiators. Azo compounds are widely used as free radical polymerization initiators. The most important (Table 7) are symmetrical azodinitriles which are synthetized from hydrazine, a ketone and HCN

Table 7. Some azo polymerization initiators

Compound	CAS registry no.	Structure	*mp* °C	10-h half-life decomposition temperature in toluene, °C
2,2′-azobisisobutyronitrile	[*78-67-1*]	R=R′=CH_3	ca. 100	65
2,2′-azobis(2-methylbutyronitrile)	[*13472-08-7*]	R=CH_3,R′=C_2H_5	ca. 50	67
2,2′-azobis(2,4-dimethylvaleronitrile)	[*4419-11-8*]	R=CH_3,R′=CH_2–CH–$(CH_3)_2$	45 – 70	51

The hydrazo derivative is oxidized by chlorine or hydrogen peroxide in the presence of a bromide as catalyst:

Water-soluble compounds like 2,2′-azobis(2-aminopropane) dihydrochloride [*2997-92-4*] as well as liquid azo compounds like diethyl 2,2′-azobisisobutyrate [*3879-07-0*], are under development.

Pesticides. Hydrazine-based pesticides represent the second major outlet for consumption of hydrazine. Maleic hydrazide was the first such pesticide used. It is produced by reaction of maleic anhydride with hydrazine:

3-Amino-1,2,4-triazole, obtained from cyanamide, hydrazine hydrate, and formic acid, is another general purpose herbicide:

This compound is used as a selective herbicide in vineyards and orchards; consumption is now several thousand tons per year.

Hundreds of patents have been filed for pesticide applications of hydrazine-based compounds; about fifty compounds are produced commercially [74], mostly heterocyclic compounds such as triazines, oxadiazoles, pyrazoles, pyridazines, thiadiazoles. Some representative examples are listed in Table 8.

During the period 1970 – 1980, triazines became important, examples being metribuzin and metamitron (see Table 8). A new family of fungicides based on the triazole ring is now being developed.

Information concerning structures, production, and use of these pesticides is compiled in [75–78].

Pharmaceuticals. Although representing only a small percentage of the total production, consumption of hydrazine in pharmaceuticals is very important. For example, isoniazid [*54-85-3*], the hydrazide of isonicotinic acid, was first used in the 1950s against tuberculosis.

In the 1980s and 1990s, other hydrazine-based pharmaceuticals were introduced, many of these containing the 1,2,4-triazole group. They have been used as antidepressants, antihypertensives, and as antibacterial or antifungal agents.

More recently, new pharmaceuticals, containing the 4-amino-1,2,4-triazole group and showing better efficiency [80, 81] (Table 9), have been developed.

Water Treatment. Sodium sulfite has long been used for scavenging oxygen dissolved in water in order to avoid corrosion in boilers or hot water heating systems:

$$2\,Na_2SO_3 + O_2 \longrightarrow 2\,Na_2SO_4$$

At higher temperatures, sodium sulfite may decompose to corrosive sulfide products. It can also form deposits, which affect heat transfer and may even cause pipes to rupture.

Hydrazine is used in water treatment for corrosion protection of steel in boilers. The only reaction products are nitrogen and water:

$$N_2H_4 + O_2 \longrightarrow N_2 + 2\,H_2O$$

Table 8. Some important hydrazine-based pesticides

Compound	CAS registry no.	Structure	Producer	Use
Triazoles

Table 9. Some important hydrazine-based pharmaceuticals

Compound	CAS registry no.	Structure	Producer	Use
Fluconazole	[*86386-73-4*]		Pfizer	antifungal
Anastrozole	[*120511-73-1*]		Zeneca	anticancer
Rizatriptan	[*144034-80-0*]		Merck	antimigraine
Cefazolin	[*25953-19-9*]		Smith Kline	antibacterial
Isoniazid	[*54-85-3*]		Pfizer	tuberculostat

Moreover hydrazine reacts with iron(III) oxide to form magnetite, which protects the metal surface against corrosion by water and oxygen [82–84]:

$$6\,Fe_2O_3 + N_2H_4 \longrightarrow N_2 + 4\,Fe_3O_4 + 2\,H_2O$$

Full corrosion protection is afforded by residual hydrazine concentrations lower than 0.1 ppm. Catalyzed hydrazine hydrate formulations (activated hydrazine) are commercially available and are efficient even at room temperature.

Propellants. The first large-scale use of hydrazine was as a rocket fuel. Anhydrous hydrazine is an excellent propellant; only hydrogen has a greater specific impulse, i.e., kilograms of thrust developed per kilogram of fuel consumed per second. Rocket propellants now in use include anhydrous hydrazine, monomethylhydrazine and unsymmetrical dimethylhydrazine (see Chap. 10). They are used mainly as bipropellant fuels in rockets such as Titan or Ariane.

Anhydrous hydrazine is also used as a monopropellant for satellites and spacecraft [85]. The hydrazine decomposes in a complex reaction over a catalyst to give a mixture of gases:

$$3\,N_2H_4 \longrightarrow 4(1-x)\,NH_3 + (2x+1)\,N_2 + 6x\,H_2$$

Typical catalysts are manufactured by Shell Chemical and Rocket Research. They are often based on iridium or ruthenium, deposited on alumina. Catalysts are described as spontaneous (working at room temperature) or nonspontaneous (working above 100 °C) [86].

A review on space applications and potential rocket propulsion systems has been published [87].

Fuel Cells. Fuel cells based on oxidation of hydrazine either with oxygen or hydrogen peroxide have been extensively studied. Their use is restricted to military applications because of the cost of hydrazine hydrate.

10. Derivatives

Alkylhydrazines. Monomethylhydrazine [*60-34-4*] MMH, and unsymmetrical dimethylhydrazine, [*57-14-7*], UDMH, are the most important derivatives; their major use is rocket fuels.

MMH UDMH

Monomethylhydrazine is produced commercially in the Raschig process by reaction of chloramine with methylamine:

whereas UDMH is now produced either by the chloramine route:

or by the reductive catalytic alkylation of acetic hydrazide [*1068-57-1*] with formaldehyde and hydrogen:

The preparation and properties of alkylhydrazines have been reviewed [88, 89]. Hydroxyethylhydrazine [*109-84-2*], $HOCH_2CH_2NHNH_2$ is obtained by reaction of hydrazine hydrate with ethylene oxide [90]:

tert-Butylhydrazine hydrochloride [*7400-27-3*] is used in the synthesis of pesticides.

Arylhydrazines. Aromatic hydrazines are not produced from hydrazine, except for 2,4-dinitrophenylhydrazine, which is obtained by reaction of 2,4-dinitrochlorobenzene with hydrazine hydrate. It is used as an analytical reagent for the determination of carbonyl compounds.

Phenyl hydrazines are obtained by diazotization of the corresponding anilines and reduction of the diazonium salts:

Characteristics of some of these compounds are listed in Table 10 [91, 92].

Table 10. Some aromatic hydrazines

Hydrazine	CAS registry no.	*mp*, °C	Appearance
Phenylhydrazine	[*100-63-0*]	19.6	colorless crystals
4-Tolylhydrazine	[*539-44-6*]	61	colorless crystals
3-Nitrophenyl-hydrazine	[*619-27-2*]	153	yellow crystals
2,4-Dinitrophenyl-hydrazine	[*119-26-6*]	200	red crystals
N,N′-Diphenyl-hydrazine	[*122-66-7*]	128	colorless crystals

Hydrazides. Some common hydrazides are listed in Table 11.

Table 11. Some hydrazides

Hydrazide	CAS registry number	Structure	M_r	*mp*, °C
Formic hydrazide	[*624-84-0*]	$HCONHNH_2$	60.06	54
Acetic hydrazide	[*1068-57-1*]	$CH_3CONHNH_2$	74.08	67
Propionic hydrazide	[*5818-15-5*]	$C_2H_5CONHNH_2$	88.12	40
Oxalic dihydrazide	[*996-98-5*]	$(H_2NNHCO)_2$	118.10	240 ∗
Semicarbazide	[*57-56-7*]	$H_2NCONHNH_2$	75.07	96

Carbohydrazide	[*497-18-7*]	$H_2NNHCONHNH_2$	90.09	157
Thiocarbohydrazide	[*2231-57-4*]	$H_2NNHCSNHNH_2$	106.15	171 ∗
Benzenesulfonylhydrazide	[*80-17-1*]	$C_6H_5SO_2NHNH_2$	172.21	103
Adipicdihydrazide	[*1071-93-8*]	$H_2N–NH–CO–(CH_2)_4CONH–NH_2$	174	18

∗ Decomposes

Carboxylic acid hydrazides are generally prepared by reactions of hydrazine hydrate with the corresponding methyl or ethyl ester:

Diacids can lead to polyhydrazides which dehydrate on heating to give polyoxadiazoles, which exhibit high thermal stability. Hydrazine carboxamide and carbohydrazide are produced from hydrazine hydrate and urea, depending on the excess of urea used:

Hydrazine carbothioamide (thiosemicarbazide) is made from CS_2 and hydrazine, and thiocarbohydrazide from CS_2, ammonia, and hydrazine [93–95].

Heterocycles. A few simple heterocycles are used as synthetic building blocks [96]. The most important heterocycle industrially is 1,2,4-triazole, which is produced from hydrazine and formamide [97, 98].

1,2,4-Triazole is a white solid, *mp* 120 °C. It is a valuable building block in the production of many fungicides.

Miscellaneous Derivatives. Different types of derivatives have found application in various industrial fields. For example, in photography, heterocycles such as triazoles, tetrazoles, 2,5-dimercapto-1,3,4-thiadiazole are used as stabilizers, fog inhibitors, or sensitizers.

A number of hydrazine derivatives are useful explosives, including the simple salts such as the nitrate [*37836-27-4*], perchlorate [*13762-80-6*], azide [*14662-04-5*], and aminoguanidine derivatives [85].

Aminoguanidine bicarbonate [*2582-30-1*], manufactured industrially from cyanamide [*420-04-2*] hydrazine, and carbon dioxide [99], is now largely used for the synthesis of various heterocycles useful in the production of pharmaceuticals, agrochemicals, and lube oil additives.

11. Economic Aspects

Considerable growth in hydrazine production capacity took place during the period 1960–2000 (Fig. 7). Estimated capacities for major producers, together with the production process used, are listed in Table 12. Total capacity (western world, 2000) is ca. 90 000 t of hydrazine hydrate. However, to be accurate, one must add to

Figure 7. Installed hydrazine capacity for various countries
UK, United Kingdom; US, United States; J, Japan; F, France; G, Germany; C, China; R, Russia; K, Korea

this capacity, the captive production of crude hydrazine hydrate (30 000 t/a) associated with the direct azodicarbonamide manufacture in Asia. Thus the total world capacity of hydrazine hydrate is ca. 120 000 t/a. Approximate consumption of hydrazine according to application is shown in Figure 8.

Table 12. Producers of hydrazine hydrate, estimated capacities, and process used (1998)

Country	Producer	Capacity, 10^3 t	Process

Russia	Kuybichev	4	Raschig

Figure 8. Hydrazine consumption

12. Toxicology and Occupational Health

Hydrazine is highly toxic, even in dilute solution, and must be handled with care. No antidote to hydrazine is known; appropriate treatment must be based on the symptoms observed.

Contact of the liquid with the skin and the eyes should be avoided. Irritation, damage due to alkalinity, dermatitis, or allergy may result. Inhalation may cause irritation or damage to the nose, throat, and lungs. Ingestion may induce convulsions and depression of the central nervous system. Repeated exposure to hydrazine may result in damage to the lungs, liver, or kidneys.

The acute and chronic toxicity of hydrazine and its derivatives have been examined in detail; reviews are available [100–103].

The results of experiments on animals are listed in Table 13. Long-term studies with laboratory animals indicate that hydrazine is mutagenic and carcinogenic; this has not, however, been demonstrated for humans.

Table 13. Acute toxicity of hydrazine

Animal	Nature	LD_{50}, mg/kg
Mouse	intravenous	58
	oral	58
Rat	intravenous	55
	oral	60
Guinea pig	cutaneous	190
Rabbit	intravenous	25
Monkey	intraperitoneal	20

The threshold limit value (TLV) has been fixed at 0.1 ppm (0.13 mg/mm^3). The olfactory detection limit is between 3 and 5 ppm.

1. Introduction

Hydrazoic acid itself has little industrial significance; the most important salts are sodium azide and lead azide.

The oldest process for preparing both the acid and the salts is based on diazotization of hydrazine and its salts [1, 2]. The method still most widely used today for production of sodium azide is the reaction of sodium amide with dinitrogen monoxide. This process was introduced industrially in 1924, but not patented until 1935 [3].

The original use of sodium azide was the safe production of lead azide, a fulminating (detonating) agent. Lead azide now constitutes only a small part of the total consumption of the sodium salt. By far the major proportion is used in the organic chemical industry. Increasing importance is ascribed to the use as a gas generator fuel that produces nontoxic nitrogen.

The toxicity and the unsettled question of potential carcinogenicity [4] make special workplace safety measures imperative.

2. Physical Properties of Sodium Azide

Sodium azide [*26628-22-8*], NaN_3, M_r 65.01, is a white, odorless, crystalline substance. Some physical properties of sodium azide are as follows:

mp	275 °C (decomp.)
Density (20 °C)	1.846 g/cm^3
Vapor pressure (20 °C)	1 Pa
Solubility in 100 mL water (15 °C)	41.0 g

Thermal decomposition occurs at 300 °C with formation of sodium metal and nitrogen.

3. Chemical Properties of Sodium Azide and Hydrazoic Acid

Heavy-metal azides, which are sensitive to friction and shock, precipitate readily from aqueous solution. Acidification of sodium azide produces explosive and toxic hydrazoic acid.

Free hydrazoic acid reacts with solutions or slurries of alkali-metal or alkaline-earth hydroxides, carbonates, and hydrogen carbonates to give solutions of the corresponding azides, which can be obtained in pure form by evaporation under vacuum.

Alkyl and acyl halides react with sodium azide to form alkyl and acyl azides, respectively. Sodium azide is also used in the Curtius reaction for the production of amines. (For further details of organic syntheses with HN_3 and NaN_3, see Section 7.2.)

4. Production

4.1. Sodium Azide

The most important production process has been developed from the work of WISLICENUS, first published in 1892 [5]; it consists of two steps. In the first step, ammonia is fed into molten sodium metal, which is contained in a closed steel vessel, at 350 °C:

$$2\,Na + 2\,NH_3 \longrightarrow 2\,NaNH_2 + H_2$$

In the second step the resulting liquid sodium amide is converted to sodium azide, sodium hydroxide, and ammonia by reaction with dinitrogen monoxide at ca. 230 °C in a horizontal nickel reactor:

$$2\,NaNH_2 + N_2O \longrightarrow NaN_3 + NaOH + NH_3$$

The solid mixture is known as crude azide. Part of the crude azide is left in the reactor for the next charge; this gives better distribution of the added sodium amide and also improves the conversion. Dinitrogen monoxide is generated by decomposition of a 50 % ammonium nitrate solution at 230 °C. The latter is prepared by absorption of the ammonia liberated in the second stage and that remaining from the first stage in 50 % nitric acid. An additional absorption medium is spent acid from nitration processes that has been recycled and worked-up. Nitric acid oxidation of the waste from adipic acid production also gives dinitrogen monoxide [6].

To isolate sodium azide, the crude azide is dissolved in water and the resulting solution is clarified and then evaporated in vacuum. The separated residual crystalline material is dried at 110 °C and may be used or shipped after the agglomerates have been broken up.

The mother liquor must be evaporated at least twice. While this is being done, any residual sodium azide is decomposed by the addition of sodium nitrite and dilute nitric acid (cf. Chap. 8):

$$NaN_3 + NaNO_2 + 2\,HNO_3 \longrightarrow N_2 + N_2O + H_2O + 2\,NaNO_3$$

The yield based on sodium is ca. 90 %, when the formation of an equimolar amount of sodium hydroxide is taken into account.

In addition to the toxicity of the final product, the risk of explosion of the gas mixture is a potential hazard. Sodium amide reacts vigorously with water.

A variation of the Wislicenus process uses sodium monoxide and consists of a single step [7]:

$$2\,Na_2O + NH_3 + N_2O \longrightarrow NaN_3 + 3\,NaOH$$

Ammonia can be replaced, wholly or in part, by sodium amide:

$$Na_2O + NaNH_2 + N_2O \longrightarrow NaN_3 + 2\,NaOH$$

No gas is liberated in this process, which may thus be run at elevated pressure.

Formation of sodium amide in liquid ammonia [8–10] and azide reaction in liquid ammonia or high-boiling hydrocarbons [11, 12] have also been reported.

When dinitrogen monoxide is added before amide formation is complete, nitrogen is given off in the one-step reaction rather than ammonia. The yield of sodium azide with respect to sodium hydroxide is less favorable [13]:

$$4\,Na + 3\,N_2O + NH_3 \longrightarrow NaN_3 + 3\,NaOH + 2\,N_2$$

Liquid ammonia [14, 15] or ethanol [11] can be used to separate the sodium hydroxide.

By following the basic experiments of CURTIUS and THIELE, production by diazotization of hydrazine has been developed further [16–18]:

$$N_2H_4 + C_2H_5ONO + C_2H_5ONa \longrightarrow NaN_3 + 2\,C_2H_5OH + H_2O$$

The ethyl nitrite required for this reaction is produced from ethanol and sodium nitrite. A serious drawback to the use of this process is the carcinogenicity of hydrazine and its salts (→Hydrazine).

4.2. Hydrazoic Acid

Hydrazoic acid is liberated as a gas by decomposition of sodium azide solution with dilute sulfuric acid. A nonexplosive gas mixture is formed by simultaneous dilution with air or nitrogen to a concentration of less than 15 %. Aqueous solutions of ca. 10 % that are safe to handle can be obtained by concentration of dilute solutions. Solutions with a hydrazoic acid content in excess of 20 % are liable to decompose explosively.

5. Quality Specifications and Analysis

In accordance with manufacturers specifications, sodium azide must fulfill the following requirements:

Color, form	White, crystalline
Azide content	99.0 % (min.)
Alkalinity	0.1 % (max.)
Water	0.1 % (max.)
Insolubles	0.1 % (max.)
Chloride (as NaCl)	0.05 % (max.)
Sulfate (as $BaSO_4$)	0.05 % (max.)
Carbonate	0.05 % (max.)
Nitrate	0.05 % (max.)
Iron	0.05 % (max.)

The azide content is determined titrimetrically by addition of an excess of cerium (IV) salt and back titration with oxalic acid.

On testing for nitrate, acidic diphenylamine solution must not turn blue when sodium azide is added.

Azides may be detected with strips of filter paper soaked in 10 % iron(III) chloride solution. This test is highly sensitive because of the formation of the intensely colored complex ion $[Fe(N_3)_6]^{3-}$.

6. Storage and Transportation

Dry sodium azide is stable for years if stored in sealed containers at room temperature. Sodium azide is packed in sheet-iron drums lined with polyethylene sacking.

In accordance with regulations concerning dangerous substances, sodium azide must be marked as a poison. The MAK value is 0.07 ppm or 0.2 mg/m^3.

Transportation codes:

United Kingdom Blue Book:	Poison and IMDG Code E 6165
United States CFR 49:	Paragraph 172.101 Poison B
ICAO/IATA-DGR:	Class 6.1 UN no. 1687

7. Uses

7.1. Salts

Sodium azide is the starting material for other metal azides. Nitrogen is released during thermal decomposition of sodium azide. The reaction is exothermic and is initiated by application of heat. In gas generators, the sodium metal formed is oxidized and reacts with silicon oxide or boron oxide to form sodium silicate or borate, respectively.

Sodium azide is used in automobile safety devices, e.g., steering-wheel air bags, where instantaneous delivery of cold, dust-free, and nontoxic gas is of utmost importance in preventing injury to the driver.

Lead azide is used as a detonating (fulminating) agent (→Explosives, Chap. 4.) [19–21]. The actual content of lead azide depends on the purpose for which it is required; the range is from 80 % to almost 100 %. The product must not contain needle-shaped crystals. Crystal growth to produce spheroids is controlled by addition of dextrin; gelatin, carboxymethyl cellulose, and polyhydroxypolycarboxylic acids or their soluble salts are also effective.

Silver azide [*13863-88-2*], AgN_3, has some advantages in certain electrical ignition systems over the less expensive lead azide.

Copper azides CuN_3 and $Cu(N_3)_2$ are hazardous products that are liable to form when sodium azide powder and hydrazoic acid are being handled. Copper azides form on objects made of copper or brass and tend to decompose explosively under mechanical load. Sieves, and dust or oil filters of pumps must be free of copper whenever a risk of contact with azides is present.

Barium azide [*18810-58-7*], $Ba(N_3)_2$, differs from other alkali-metal and rare-earth azides in that it can be precipitated directly from aqueous solutions of sodium azide and barium bromide. Barium azide is used in fluorescent light tubes to improve the light yield.

7.2. Organic Synthesis

Sodium azide is used in organic synthesis under very strict safety precautions. Reactions with sodium azide or its solutions may be carried out in plastic, glass, or enameled vessels that are free of exposed metal parts. Solid sodium azide is best stored in plastic containers. Before experiments begin, all apparatus must be checked for bare metal parts. Overheating of individual parts, (e.g., agitator shafts) should be avoided. Care must be taken to remove the poisonous and highly explosive gases resulting from formation of hydrazoic acid, and effective protection against explosion must be provided.

Reactions with sodium azide or hydrazoic acid enable a series of organic azides and derivatives to be obtained.

Substitution. The S_N2 reaction of alkyl halides with sodium azide is generally applicable in the aliphatic series. Dimethylformamide is particularly suitable as solvent. Acid chlorides react rapidly, producting the acid azides necessary for the Curtius reaction:

$$RC(=O)-Cl + NaN_3 \longrightarrow RC(=O)-N_3 + NaCl$$

Acid azides are also used in peptide synthesis because the reaction with amino acids proceeds under such mild conditions that the optically active configuration is retained.

Particularly active esters and tertiary alcohols can also react with metal azides to yield the corresponding azides. Aromatic diazonium salts react with azide ions in a type of extended Sandmeyer reaction:

$$R-N\equiv N^+ + N_3^- \longrightarrow R-N_3 + N_2$$

Addition. Olefins react with hydrazoic acid to form alkyl azides:

$$RC(H)=CR^1(H) + HN_3 \longrightarrow RCH_2-CH(R^1)(N_3)$$

Isocyanates are transformed to carbamic acid azides. Ketenes form acid azides. *Trans*-α-Azidoalcohols are formed from epoxides.

Salt Formation. Amines and phosphines form salts with hydrazoic acid. For example, triphenylphosphine reacts with 2 mol of hydrazoic acid to produce the triphenylphosphine–iminium salt.

Miscellaneous Reactions. Organic azides are used as starting materials for the preparation of heterocyclic compounds such as imidazoles, oxazoles, 1,2,3-triazoles, and 5- or 1-substituted tetrazoles:

Thermal or photochemical decomposition of organic azides occurs with evolution of nitrogen to give the corresponding nitrenes. The latter contain monovalent nitrogen and, like carbenes, undergo isomerization, insertion reactions, or addition of nucleophiles. Many azide reactions, such as their frequently explosive decomposition, ring closure, Curtius or Schmidt reactions, photochemical cross-linking in polymer systems, and ring expansion, involve nitrene intermediates.

8. Safety Precautions and Environmental Protection

In the production of sodium azide, sodium amide represents a dangerous material, because it reacts violently with water; contact with water or air during storage must therefore be prevented. As the azide reaction continues, the evolving hydrogen must be burned off outside the building or purified for further use.

All equipment and gas piping must be fitted with explosion valves or rupture membranes because all the evolved gases are explosive in a wide range of mixtures. The hazard is increased by airborne dust particles.

When handling sodium azide, its solutions, and highly volatile hydrazoic acid, impervious protective clothing must be worn. To protect the respiratory organs from dust or gases, dustproof masks must be used. Before the masks are put on, their blank metal parts must be lacquered, care being taken that the lacquer is free of pores. A supply of fresh air to the masks is advantageous.

Working materials should preferably be plastics, but nonsparking metals may also be used. Sodium azide moistened with water reacts violently when ignited, giving off a highly caustic smoke.

In the event of fire, water-containing extinguishers must not be used; dry sand and anhydrous soda (soda ash) are suitable.

Small amounts of azide-containing waste and azide dust can be decomposed harmlessly with ceric ammonium nitrate. Larger quantities must be destroyed by addition of a sodium nitrite solution followed by a mineral acid solution. Azides react with acids to give a gas cloud capable of spontaneous detonation.

9. Economic Aspects

The main producers of azides are Canadian Industries (Canada), Masuda (Japan), and Dynamit-Nobel AG (Federal Republic of Germany). Total annual production is ca. 250 t. New production plants are expected to be built in the near future because of the increasing demand from producers of automobile safety devices.

10. Toxicology and Occupational Health

Dry sodium azide, its solutions, and hydrazoic acid are extremely toxic and can be absorbed by inhalation, ingestion, and skin absorption [22, 23]. In the event of contact of the skin or mucous membranes with azides, the affected parts must be rinsed thoroughly with water.

The MAK value for sodium azide is 0.07 ppm; for hydrazoic acid, 0.1 ppm.

Even minute amounts of azides cause headache, irritation of the eyes and mucous membranes, heightened irritability and excitation, impairment of vision, shortness of breath, reduction of blood pressure, risk of collapse, and fainting. The maximum nonfatal limit is given as 0.01 g; nevertheless, 0.005 – 0.01 g can have harmful effects.

Minor complaints can be eased quickly by fresh air or by administration of oxygen. No chronic poisoning has been observed. Azides appear to be similar to cyanides and prussic acid, in their ability to affect the cytochrome oxidase system and probably become bound to methemoglobin; *p*-aminopropiophenone has been suggested as an antidote. Amyl nitrite, which is effective in prussic acid poisoning, increases the risk of collapse.

1. Introduction [1–8]

The hydrides are a large group of compounds with diverse structures and bonding types. They may be divided into four classes according to their bonding character:

1) Ionic hydrides
2) Polymeric covalent hydrides
3) Volatile covalent hydrides
4) Metallic hydrides.

The demarcation between the classes is not sharp; they merge into each other according to the electronegativities of the elements concerned.

Arranging the binary hydrides as in the periodic table (see Fig. 1, next page), the *ionic hydrides* are seen to be formed by the strongly electropositive alkali and alkaline earth metals. Beryllium hydride, which is partly covalent in character, is an exception.

The elements that form *polymeric covalent hydrides*, apart from beryllium, belong to Groups 12 (zinc) and 13 (boron). Boron occupies a special position. It forms numerous volatile hydrides with unusual structures (→ Boron Compounds, Chap. 5.1.). The hydrides of Group 13 are electron deficient; saturation is achieved in the complex hydride ions such as BH_4^- and AlH_4^-. The covalent hydrides formed by the elements of groups 14 – 17 (carbon – f luorine) are characterized by high volatility. The polarity of the element – hydrogen bond changes with increasing electronegativity of the elements. Whereas the hydrides of the metallic elements and of silicon contain hydridic (negatively polarized) hydrogen, those of the nonmetals contain acidic hydrogen, sometimes strongly so. The latter are not regarded as hydrides in the usual sense

Covalent polymeric hydrides
Covalent hydrides
Metallic hydrides

Figure 1. Periodic system of binary hydrides (the figures in the table are the Allred – Rochow electronegativities) Hydrides in parentheses are unstable at ambient temperature.

and are not discussed in the present article.

Metallic hydrides are formed by the transition metals, the lanthanides, and the actinides. The structures of these hydrides are fundamentally similar to those of metals. The compositions of the metallic hydrides can vary and are frequently nonstoichiometric. Another class of hydrogen compounds, the transition metal hydride complexes, is becoming important. In these molecular complexes the hydrogen atoms are covalently linked to a transition metal. Economically, the most important hydrides are those of the alkali and alkaline earth metals and the complex hydrides of boron and aluminum. These are mostly produced in tonnage quantities and have a wide range of applications.

2. Hydrides of the Alkali and Alkaline Earth Metals

2.1. General

The alkali and alkaline earth metals react exothermically with hydrogen at elevated temperature to form ionic hydrides:

$$2\,Na + H_2 \longrightarrow 2\,Na^+H^-$$
$$Ca + H_2 \longrightarrow Ca^{2+}H_2^-$$

The typical course of a metal – hydrogen reaction is shown in Figure 2. The rate of hydrogen uptake is shown as a function of H_2 pressure at different temperatures. At constant temperature the metal initially takes up hydrogen by dissolving it (solution phase). As more hydrogen is taken up hydride formation starts, resulting in a mixture of two phases: hydride and solution.

The pressure remains constant (plateau region) until the combined hydrogen reaches a limiting stoichiometry, after which the pressure again increases sharply until the ideal stoichiometric composition MH_2 is reached (hydride phase). In the case of the salt-like hydrides, the hydride phase is very small, i.e., the limiting stoichiometry is near to the ideal.

Figure 2. Isotherms of a hypothetical dihydride MH_2 ($T_3 > T_2 > T_1$).

For the metallic hydrides the hydride phase can become very large. It can be seen from Figure 2 that although the rate of hydride formation can be increased by increasing the temperature and the hydrogen pressure there is a penalty: heating salt-like or metallic hydrides causes reversible decomposition into the elements. The dissociation pressure in the plateau region is given over a wide range of temperature by the following relationship:

$$\log_{10} p_{\mathrm{H2}} = -\frac{A}{T} + \mathrm{B}$$

Values for the constants A and B are given in the literature [2,4]. Plateau dissociation pressures of some alkali and alkaline earth metal hydrides are shown in Figure 3. The noticeable instability of MgH_2 may be attributed to a transition towards the behavior of BeH_2 and other covalent polymeric hydrides.

Figure 3. Plateau dissociation pressures of alkali and alkaline earth metal hydrides as a function of temperature.

The other hydrides of the alkali and alkaline earth metals possess an ionic structure with negatively charged hydrogen ions, as illustrated by the following:

1) Electrolysis of a molten salt mixture of the hydrides with alkali metal halides and hydroxides causes liberation of hydrogen at the anode.
2) Lattice energy calculations based on an ionic model give results in good agreement with experimental values.
3) They are insoluble in inert organic solvents.

The crystal structures of the alkali metal hydrides are of the rock salt (NaCl) type, the alkaline earth metal hydrides have structures of the $PbCl_2$ type, only MgH_2 having the rutile (TiO_2) structure [9]. The more important physical properties are given in Table 1, see next page. It should be noted that the density of the hydrogen (grams of hydrogen per cubic centimeter of hydride) in some of these hydrides is sometimes appreciably higher than that of liquid hydrogen itself ($\varrho = 0.0710$ g/cm^3 at 20.4 K).

The *chemical properties* of the aforementioned hydrides are determined by their high basicity and reducing power. The hydride ion

reacts irreversibly with compounds containing acidic protons, liberating hydrogen:

$$M^+H^- + H^{\delta+}X^{\delta-} \longrightarrow M^+X^- + H_2$$

X = halogen, OH, OR, HNR, SR

The reactivity of the hydrides increases from lithium to cesium and from magnesium to barium; it is also strongly dependent on particle size. Superactive alkali metal hydrides are obtained by the hydrogenation of alkali metal alkyls in hexane in the presence of a strong base (e.g., tetramethylethylenediamine) [10, 11]. These superactive hydrides can be used to metallate compounds that do not react with commercially available hydrides. The high reducing power of the ionic hydrides ($H^- \rightarrow 1/2\,H_2 + e^-$; $E^0 = -2.23$ V) is used in metallurgical processes (see Sections 2.3 and 2.7). The reduction of organic compounds is better carried out with the complex hydrides obtained by reaction of alkali or alkaline earth metal hydrides with Lewis acids (see Chap. 3).

Analysis of these hydrides is carried out using the exothermic reaction with water, e.g.,

$$LiH + H_2O \longrightarrow LiOH + H_2$$

The hydrogen liberated is determined volumetrically and the alkaline solution titrated with acid.

2.2. Lithium Hydride

Properties (see also Table 1). Pure lithium hydride forms colorless, cubic crystals. The commercial product contains traces of impurities, e.g., unreacted lithium metal, and is consequently light gray or blue. Physical and thermodynamic data on lithium hydride and deuteride have been determined in detail [12, 13]. Lithium hydride is thermally very stable (see Fig. 3), being the only ionic hydride that melts without decomposition at atmospheric pressure (*mp* 688 °C). In contrast to the other alkali metal hydrides, lithium hydride is slightly soluble in inert polar organic solvents such as ethers. It forms eutectic mixtures with a large number of salts [2].

Lithium hydride is stable in dry air but ignites at increased temperature. In moist air it is hydrolyzed exothermically; finely divided material can ignite spontaneously. At elevated temperature, it reacts with oxygen to form lithium oxide, with nitrogen to form lithium nitride and hydrogen, and with carbon dioxide to form lithium formate. With compounds containing acidic hydrogen atoms (e.g., alcohols) it reacts with liberation of hydrogen:

$$R{-}OH + LiH \longrightarrow R{-}OLi + H_2$$

Reaction of lithium hydride with water is extremely violent. Above 180 °C it reacts with silicates (as does metallic lithium) so that apparatus made of glass, silica, porcelain, or enamelled materials should not be used. The nucleophilic properties of lithium hydride enable it to be used in condensation reactions, e.g., of aldehydes and ketones, and reductions, e.g., the conversion of acyl chlorides to aldehydes. Nevertheless, sodium hydride is more effective for

condensations and complex hydrides for reductions. Another characteristic reaction is the addition of the hydride anion to the coordinatively unsaturated Lewis acids (see Chap. 3).

Production. Lithium hydride is manufactured on a large scale by combination of the elements at 700 – 900 °C:

$$2\,Li + H_2 \longrightarrow 2\,LiH$$

The lithium metal is held in an iron crucible of low-carbon content enclosed in a vessel of highly alloyed scale-resistant steel. After being melted under vacuum, the metal is reacted with hydrogen at 700 °C and ca. 0.1 MPa. The strongly exothermic reaction is controlled by the hydrogen feed rate. The denser lithium hydride sinks to the bottom of the crucible, leaving the reactive metal at the surface. On completion of the reaction, the melt is slowly cooled and the blue-gray crystalline block is broken down to the required particle size. The product has a purity of 98 – 99 % and is supplied in the form of lumps or powder with a bulk density of ca. 0.29 kg/L. The commercial producers are Chemetall GmbH, Lithium Corporation of America, and Ventron Corporation. The catalytic hydrogenation of lithium at atmospheric pressure and 25 – 50 °C in tetrahydrofuran (THF) in the presence of $TiCl_4$ – naphthalene has been reported [14]. This process has not yet been used on an industrial scale.

Uses. Most lithium hydride, which is produced in tonnage quantities, is used as a raw material in the production of lithium aluminum hydride (see Section 3.8) and lithium amide (→ Lithium and Lithium Compounds):

$$4\,LiH + AlCl_3 \longrightarrow LiAlH_4 + 3\,LiCl$$
$$LiH + NH_3 \longrightarrow LiNH_2 + H_2$$

Another important use is in the production of silane by the Sundermeyer process. Lithium hydride is treated with tetrachlorosilane, the reaction medium being a molten LiCl – KCl eutectic:

$$4\,LiH + SiCl_4 \longrightarrow SiH_4 + 4\,LiCl$$

In the industrial process this reaction is linked with the regeneration of lithium hydride by electrolysis of the molten salt and hydrogenation of the lithium metal in situ [1, 15].

The reaction can also be carried out in high-boiling solvents by the addition of small amounts of lithium aluminum hydride, e.g., in the production of disilane [16]:

$$2\,Si_2Cl_6 + 3\,LiAlH_4 \longrightarrow 2\,Si_2H_6 + 3\,LiCl + 3\,AlCl_3$$
$$4\,LiH + AlCl_3 \longrightarrow LiAlH_4 + 3\,LiCl$$

The reaction of lithium hydride with boron trialkyls gives trialkylborohydrides, which are soluble in THF.

$$LiH + R_3B \longrightarrow LiR_3BH$$

When R is an ethyl group the product is known as Super-Hydride (see Section 3.3). Trialkylborohydrides are used in organic chemistry as regio- and stereoselective reducing agents [17].

As a result of its high hydrogen content (hydrolysis of 1 g LiH produces 2.5 L of H_2 at STP), lithium hydride is used as a transportable hydrogen source, e.g., for inflatable rubber dinghies and balloons. Lithium deuteride [*13587-16-1*], LiD, is commercially available (Chemetall) and is used for labeling organic compounds with deuterium.

2.3. Sodium Hydride [18]

Properties (see also Table 1). Pure sodium hydride forms colorless cubic crystals; however, the commercial product contains traces of sodium metal, giving it a light gray color.

At atmospheric pressure, sodium hydride slowly evolves hydrogen above 300 °C. At 420 °C decomposition is rapid but melting does not take place. Sodium hydride is a salt and therefore insoluble in inert organic solvents. It dissolves in molten sodium hydroxide, in sodium – potassium alloys and in molten LiCl – KCl eutectic mixtures (352 °C). Sodium hydride is stable in dry air but ignites above 230 °C, burning to form sodium oxide (for fire precautions see Chap. 6). It is hydrolyzed rapidly in moist air and as a dry powder it is spontaneously flammable. Sodium hydride reacts extremely violently with water, the heat of hydrolysis being sufficient to ignite the liberated hydrogen. It reacts with carbon dioxide to form sodium formate.

The most important chemical property of sodium hydride is its basicity. Sodium hydride reacts irreversibly with a large number of compounds containing acidic hydrogen atoms, including alcohols, phenols, thiols, and amines, but also with weak carbon acids such as ketones, carboxylic esters, and acetylenic hydrocarbons. The carbanions formed play an important role in synthetic organic chemistry [18].

Sodium hydride reacts with Lewis acids to give addition complexes, e.g., with esters of boric acid it yields sodium borohydride (see Section 3.4). The practicability of these reactions is strongly dependent on the particle size and surface area of the sodium hydride because of the low solubility. Activators such as trialkylboranes and trialkylalanes can be used to accelerate the reaction, e.g., in the production of sodium aluminum hydride (see Section 3.10).

Sodium hydride is a poor reducing agent because of its high basicity and its insolubility in inert organic solvents. If the sodium hydride is complexed with alcoholates and metallic salts, complex reducing agents are formed that can reduce halides, alkenes, and ketones. The use of specific metal salts makes it possible to reduce the carbonyl group or the carbon – carbon double bond of α,β-unsaturated ketones regioselectively [19]. At high temperature, e.g., in molten sodium hydroxide, sodium hydride is strongly reducing and is used in the production of finely powdered metals and in metal surface treatment.

Production. The best method of synthesis is to react molten sodium metal with hydrogen in mineral oil. A satisfactory rate of reaction is obtained by finely dispersing the sodium with a high-shear turbine mixer (ca. 8000 rpm). The reaction is very rapid at 250 – 300 °C and atmospheric pressure and can be operated continuously [20]. A large part of the NaH – oil dispersion produced is used directly for production of sodium borohyride.

Sodium hydride is available commercially as 80 % and 60 % dispersions in mineral oil. The light-gray pourable material has an average particle size of 10 µm (Degussa, Chemetall, Ventron). The oil protects the surface of the highly reactive sodium hydride, which easily becomes passivated by the slightest atmospheric exposure or, worse, can ignite on longer contact with air.

Handling is facilitated by packing the material in bags made of plastic sheet soluble in organic solvents. For use in metal-descaling baths, the sodium hydride is produced directly in molten sodium hydroxide.

Uses. In the United States, a high proportion of the sodium hydride is used in the production of sodium borohydride (see Section 3.4). In the metal industry it is used as a solution (0.2 – 2.5 %) in molten sodium hydroxide for the descaling of metal surfaces [21]. The high reducing power of the hydride results in the conversion of the surface oxide to metal:

$$Fe_3O_4 + 4\,NaH \longrightarrow 3\,Fe + 4\,NaOH$$

Its ability to reduce metal salts is used in the production of powdered metals, often with very small particle size and large surface area [22].

The main application of sodium hydride is in organic synthesis [18, 23]. Its strong basicity is used in the production of ethers (Williamson synthesis), alkylation of amines, and alkylation of the α-carbon atoms of ketones, esters, carboxylic acids, and nitriles. The carbanions produced with sodium hydride are used in many

condensation reactions, (e.g., Claisen, Stobbe, and Dieckmann). These reactions are important in the production of pharmaceutical intermediates [24]. It should be noted that uncontrollable reactions have been reported when dimethylformamide was used as solvent [25]. Sodium hydride has several advantages compared with other reagents such as sodium alkoxides, sodium amide, or sodium metal: it reacts very quickly under mild conditions and apart from hydrogen no other byproducts (e.g., alcohols or water) are formed.

2.4. Potassium Hydride

Properties (see also Table 1). Potassium hydride is a considerably stronger base than lithium hydride or sodium hydride. It is able to remove protons from tertiary alcohols and ketones, a reaction that either does not occur or is very slow when sodium hydride is used [26]. Potassium hydride also reacts with weak Lewis acids,

converting sterically hindered boron trialkyls to the corresponding sterically hindered complex borohydrides:

$$KH + R_3B \xrightarrow{THF} KBHR_3$$

Potassium tri-*sec*-butylborohydride [*54575-49-4*] solution in tetrahydrofuran (THF) is sold as K-Selectride (Aldrich). These compounds may be used for highly stereoselective reductions, e.g., of ketones [26]. Chemical rearrangements induced by potassium hydride are important in organic chemistry. Furthermore, in combination with other reagents potassium hydride acts as a catalyst in the polymerization of alkenes and dienes [26].

Production. The process already described for sodium hydride manufacture can be used, i.e., hydrogenation of a metal dispersion in a high-boiling mineral oil. In addition, a process has been described in which phenanthrene acts as catalyst in the hydrogenation of potassium at atmospheric pressure and at 90 – 200 °C in hydrocarbon solvents such as nonane [27–29]. This catalytic reaction is specific for potassium and cannot be used with the other alkali metals. Potassium hydride is available in laboratory quantities only as a 20 – 35 % dispersion in oil.

2.5. Beryllium Hydride

Properties (see also Table 1). Beryllium hydride is a white, involatile, amorphous powder. The pure compound decomposes with evolution of hydrogen at about 220 °C. It is fairly stable to air at room temperature and is rapidly hydrolyzed by water if this is acidified. Beryllium hydride containing ether decomposes at ca. 130 °C and reacts very violently with water. Crystalline beryllium hydride ($\varrho = 0.78$ g/cm^3) is obtained when the LiH-doped amorphous material is densified by compression at 620 MPa and 200 °C [29]. The hydrogen density in this material (0.1425 g/cm^3) is twice that of liquid hydrogen. All forms of the covalent hydride possess a structure with Be–H–Be 3-center bonds. It is insoluble in inert organic solvents but reacts with tertiary amines at ca. 160 °C to form stable adducts. Beryllium hydride and its derivatives are extremely poisonous (→ Beryllium and Beryllium Compounds, Chap. 15.).

Production. The only known method of producing high purity beryllium hydride (95 – 98 wt % BeH_2) is the pyrolysis of di-*tert*-butylberyllium diethyl etherate in a high boiling hydrocarbon at 200 °C [30]:

$$((CH_3)_3C)_2Be \cdot O(C_2H_5)_2 \longrightarrow BeH_2 + 2\,(CH_3)_2C{=}CH_2 + O(C_2H_5)_2$$

The many attempts to react beryllium compounds (e.g., BeR_2, $BeCl_2$) with hydrides (e.g., $LiAlH_4$, $HAlR_2$) have given disappointing results, and direct synthesis from the elements has not proved possible.

Uses. Beryllium hydride has attracted considerable interest as a rocket fuel on account of its high heat of combustion. It has also been considered as a moderator for nuclear reactors. Methods of preparing and densifying the pure

compound are described in a large number of patents. However, the toxicity has always been a serious barrier to its commercial exploitation.

2.6. Magnesium Hydride

Properties (see also Table 1). Pure magnesium hydride is a white, nonvolatile powder. Although its properties are predominantly salt-like, it shows signs of a transition towards the covalent polymeric hydride structure of compounds such as beryllium and aluminum hydride. Its enthalpy of formation (see Table 1) and thermal stability (see Fig. 3) are considerably lower than those of the homologous calcium hydride. Magnesium hydride decomposes without melting at 280 °C. Its reactivity depends on the method of preparation. The product obtained by direct synthesis from the elements is stable in air. Nevertheless, if it is prepared by pyrolysis of dialkyl magnesium or by reaction of lithium aluminum hydride with dimethyl magnesium, the product is very pure and finely divided and ignites spontaneously on contact with air.

Production. Magnesium hydride is synthesized industrially from the elements at 300–400 °C and 10–15 MPa hydrogen pressure in a rotary autoclave provided with steel grinding balls:

$$Mg + H_2 \longrightarrow MgH_2$$

The commercial product is gray due to the presence of impurities, being about 97 % pure (Ventron). Less drastic reaction conditions are required when a homogeneous catalyst is used [31–33]. The hydrogenation can be carried out at 60–70 °C and 8 MPa in THF in the presence of halides of chromium, titanium, or iron and magnesium–anthracene complex. In contrast to the product from an uncatalyzed synthesis, this has a high specific surface area (90 m^2/g compared with 0.5 m^2/g), and is very reactive and pyrophoric.

Uses. Magnesium hydride contains a high proportion of hydrogen (7.65 wt %), which can be liberated by heat. The catalytically produced compound displays rapid rates of hydrogenation and dehydrogenation and it is therefore of interest as a hydrogen reservoir [34]. The high activity of catalytically produced magnesium hydride also enables it to take part in an addition reaction with 1-alkenes to form organomagnesium compounds [35]:

$$MgH_2 + 2\,CH_2{=}CHR \longrightarrow Mg(CH_2CH_2R)_2$$

These dialkylmagnesium compounds have become industrially important in the production of very active Ziegler catalysts.

The Mg–H_2 system can also be used for the simultaneous removal and purification of pure hydrogen from gas mixtures [36]. Magnesium hydride is also used as a drying agent for organic solvents and gases and in chemical syntheses.

2.7. Calcium Hydride

Properties (see also Table 1). Pure calcium hydride crystallizes in the form of colorless, hexagonal prisms, but the industrial product contains some calcium metal and is consequently gray. On heating, calcium hydride decomposes without melting. In keeping with its salt-like character it is insoluble in inert solvents but dissolves in molten LiCl–KCl eutectic mixtures (352 °C). Calcium hydride can be safely handled in air, but is slowly attacked and crumbles to powder if the air is moist. It reacts with dry oxygen or nitrogen if heated above 500 °C, forming the oxide or nitride, respectively. Once ignited, it burns with a strongly exothermic reaction:

$$CaH_2 + O_2 \longrightarrow CaO + H_2O$$

The reaction of calcium hydride with water is also very exothermic. Heating is necessary to initiate the reaction with alcohols to form alcoholates. The reaction with ammonia takes place at 700 °C with formation of calcium amide. At high temperature (600–1000 °C) calcium hydride is a powerful reducing agent.

Production. Calcium hydride is produced industrially by synthesis from the elements at 400 °C and atmospheric pressure:

$$Ca + H_2 \longrightarrow CaH_2$$

The reaction is strongly exothermic and is controlled by means of the hydrogen feed rate.

The commercial product contains 90–96 % CaH_2 (Degussa, Ventron). The main impurities are calcium metal (≤ 6 %) and calcium oxide (≤ 1 %). It is available as powder, granules, or lumps.

Uses. Calcium hydride is used to obtain metallic elements (e.g., Ti, Zr, V, Nb, U, and Th) from the oxides because of its very powerful reducing properties at elevated temperature (600–1000 °C):

$$2\,CaH_2 + TiO_2 \longrightarrow Ti + 2\,CaO + 2\,H_2$$

This process, the Hydrimet process, yields finely divided metal, the calcium oxide and excess calcium hydride being removed by washing with dilute acids. Powdered oxide mixtures are converted to powdered alloys.

The actual reducing agent in this process may not be the calcium hydride, but metallic calcium produced by thermal decomposition. Metal halides are also reduced to metal in a similar process. Another application of calcium hydride is in drying solvents and gases. As it does not strongly promote condensation reactions, it may be used to dry ketones, esters, higher alcohols, phenols, amines, and halogenated hydrocarbons in addition to the inert solvents; a water content of 1 ppm is attainable. An interesting application is the determination of the water content of diesel fuel and kerosene by reaction with calcium hydride and determination of the volume of hydrogen evolved. This water content is important in adjusting the optimum compression ratio of an engine.

3. Binary and Complex Hydrides of the Boron Group

3.1. General

All the elements of Group 13 (Boron group) form polymeric hydrides $(EH_3)_x$. The monomers EH_3 are strong Lewis acids and are unstable. Borane (BH_3) achieves electronic saturation by dimerization to form diborane (→ Boron Compounds, Chap. 5.1.). All other hydrides in this group attain closed electron shells by polymerization. Aluminum hydride, alane, $(AlH_3)_x$, has been extensively investigated, the hydrides of gallium indium and thallium much less so [3].

In contrast to the ionic and metallic hydrides, the hydrides of the boron group cannot be synthesized directly from the elements. A general method of preparation is to react a halide of the element with lithium hydride in an ether:

$$4\,LiH + ECl_3 \longrightarrow LiEH_4 + 3\,LiCl$$
$$3\,LiEH_4 + ECl_3 \longrightarrow 4\,EH_3 + 3\,LiCl$$

The complex hydride $LiEH_4$ is formed as an intermediate. The hydride EH_3 is then produced as a soluble etherate that rapidly polymerizes.

The binary hydrides can be stabilized by forming solvates or other addition compounds. Their stability decreases from boron to thallium. Borane and alane form a large number of donor–acceptor complexes whose properties are strongly dependent on the nature of the donor molecule. The main donor compounds are ethers, amines, phosphines, and hydride ions. Of particular interest are the hydride complexes of borane, the tetrahydridoborates $M(BH_4)_n$, and of alane, the tetrahydridoaluminates $M(AlH_4)_n$. The most industrially important complex hydrides are sodium tetrahydridoborate $NaBH_4$ and lithium tetrahydridoaluminate $LiAlH_4$. These are produced in tonnage quantities and used mainly as reducing agents in organic chemistry. Many other hydridoborates and hydridoaluminates are produced from these starting materials [37, 38]. The bonding characteristics and hence the properties of the complex hydrides are largely determined by the electronegativity difference between the metal atom and boron or aluminum. If this difference is large, e.g., in $NaBH_4$ or KBH_4, the compound is highly ionic and has a high melting point. If it is small, as with $Al(BH_4)_3$, the BH_4 group is covalently bonded and the compound is volatile (*bp* 44.5 °C). The reactivity of the complex hydrides corresponds to the stability, i.e., to the decomposition temperature. Thus, $NaBH_4$ (decomposition temperature > 400 °C) reacts relatively slowly with water (see Section 3.4), whereas $Al(BH_4)_3$ (decomposition temperature 100 °C) is instantly hydrolyzed and reacts explosively with moist air. The hydridoaluminates are very much less stable than the hydridoborates and therefore considerably more reactive, e.g.,

$NaBH_4$ is a much milder reducing agent than $NaAlH_4$ (decomposition temperature 210 °C).

The properties of the complex hydrides can also be varied by the introduction of substituents on the boron or aluminum atom. An example is lithium tri-*tert*-butoxyaluminum hydride (see Section 3.9). This is a much milder reducing agent than $LiAlH_4$ because of the steric hindrance affecting the single remaining hydride ligand. Solubility is also affected by substitution. Thus, whereas $NaAlH_4$ is completely insoluble in hydrocarbons, it becomes soluble in toluene when alkyl groups are introduced (see Section 3.12).

The physical properties of the important commercially available complex hydrides are listed in Table 2. Their reducing properties towards various organic functional groups are given in Table 3. The variation in reducing properties and solubility (see Tables 4 and 5) represents a wide choice of reagents with which many difficult reductions can be achieved. Reductions with complex hydrides are rapid under mild conditions, give good yields of pure products, and are often remarkably selective; this accounts for their wide field of application in the chemical industry. Without these highly reactive and selective reagents the multi-step syntheses of natural products or pharmaceuticals would be inconceivable. The literature on the use of complex hydrides in preparative organic chemistry is unusually extensive, and there are good review articles and monographs on the subject [5, 39].

Table 3. Reducing properties of various hydrides towards functional groups

	Aldehydes	Ketones	Epoxides	Acyl chlorides	Esters	Anhydrides	Carboxylic acids	Acyl amides	Nitriles	Nitro compounds	Alkyl halides	Tosylhydrazones	Alkenes	Alkynes

3.2. Lithium Tetrahydridoborate

Properties (see also Table 2). Lithium tetrahydridoborate (known industrially as lithium borohydride or lithium boranate), $LiBH_4$, is a white, microcrystalline powder that decomposes at the melting point (280 °C) with considerable evolution of hydrogen. It is stable in vacuum to about 200 °C. It is extremely hygroscopic, being rapidly decomposed by moist air, sometimes with spontaneous ignition. It is therefore stored and handled in an atmosphere of nitrogen or argon. It is hydrolyzed only slowly by water at 0 °C:

$$LiBH_4 + 2\,H_2O \longrightarrow LiBO_2 + 4\,H_2$$

By acidification of the solution or by addition of certain metal salts as catalysts, the hydrolysis is rapid and large volumes of hydrogen are liberated (4.11 L/g at STP). Lithium borohydride is a more powerful reducing agent than sodium borohydride although much less reactive than lithium aluminum hydride.

Lithium borohydride is used for the selective reduction of esters, carboxylic acids, amides, and epoxides in preference to other functional groups such as nitriles, nitro compounds, and halides [5]. The effect of solvents has been investigated [40]; diethyl ether and tetrahydrofuran are preferred. The addition of a stoichiometric amount of methanol leads to a very large increase in reducing power without significantly affecting the selectivity. Among the reactions of lithium borohydride with inorganic compounds [1,5,41], special mention should be made of reactions yielding borohydrides or hydrides of other metals, e.g.,

$$4\,LiBH_4 + ZrCl_4 \longrightarrow Zr(BH_4)4 + 4\,LiCl$$

Production. Industrial production of lithium borohydride makes use of the heterogeneous metathetical reaction between LiCl or LiBr and sodium borohydride in ethers (diethyl ether, tetrahydrofuran) or amines:

$$NaBH_4 + LiX \longrightarrow LiBH_4 + NaX$$

X = Cl, Br

The mixture is ball-milled while the reaction takes place in order to ensure a satisfactory rate of reaction and a good yield (up to 90 %) [42]. Synthesis from the elements is not used industrially.

The commercial product (Chemetall, Ventron) has a bulk density of 0.6 – 0.7 g/cm^3 and a purity of 94 %.

Uses. Lithium borohydride is used to a limited extent as a selective reducing agent in organic chemistry. It has been investigated as a means of storing hydrogen, but has not been used on an industrial scale for this purpose [43].

3.3. Lithium Triethylhydridoborate

Lithium triethylborohydride, Super-Hydride, $LiBH(C_2H_5)_3$, is the most frequently used alkyl substituted complex borohydride. It is produced by reaction of lithium hydride and triethyl borane in THF solution at room temperature:

$$LiH + B(C_2H_5)_3 \longrightarrow LiBH(C_2H_5)_3$$

In the pure state it is a colorless, viscous liquid that is oxidized and hydrolyzed in moist air; it may ignite on contact with water or alcohols.

It is commercially available in limited quantities as a 12 % solution in THF under the name Super-Hydride (Aldrich). This solution is quite stable provided that air and moisture are excluded [17]. This reagent possesses considerably greater nucleophilicity than, say, lithium

aluminum hydride, and is therefore used for the reductive substitution of electronegative functional groups, enabling the rapid and quantitative reduction of alkyl halides to the corresponding hydrocarbons to be carried out [23]. Another reaction with excellent yields is the reductive deoxygenation of tosylates (toluenesulfonates) [44].

The steric hindrance of the hydrogen atom linked to boron by the ethyl groups leads to reactions with marked regio- and stereoselectivity.

3.4. Sodium Tetrahydridoborate

Properties (see also Table 2). Sodium tetrahydridoborate, sodium borohydride, sodium boranate, $NaBH_4$, is a white, slightly hygroscopic salt that is stable in dry air up to 300 °C. It decomposes slowly in a vacuum at 400 °C, quickly above 550 °C, with liberation of hydrogen; *mp* (under 1 MPa H_2) 505 °C. If ignited with a naked flame it burns quietly. (For fire precautions see Chapter 6). It can be stored in an airtight container for many years without decomposition. Sodium borohydride absorbs water from moist air to form the dihydrate, $NaBH_4 \cdot 2\,H_2O$, which slowly decomposes to form sodium metaborate and hydrogen. In acidic media rapid hydrolysis takes place:

$$BH_4^- + H^+ + 3H_2O \longrightarrow H_3BO_3 + 4\,H_2;$$

$\Delta H = -372$ kJ/mol.

Sodium borohydride, in keeping with its ionic character, is readily soluble in polar solvents, especially protic compounds such as water, lower alcohols, and amines (see Table 4).

With a few solvents it forms isolable though not very stable solvates [37]. In protic solvents, solvolysis occurs, and hydrogen is evolved:

$$NaBH_4 + 4\,ROH \longrightarrow NaB(OR)_4 + 4\,H_2$$

Thus, sodium borohydride is 80 % decomposed after 1 h in methanol at 0 °C, 6 % decomposed after 1 h in ethanol at 60 °C, but is stable in 2-propanol and *tert*-butanol and at room temperature. The solubility and stability in water, the most frequently used solvent, have been extensively investigated [45] (see Fig. 4). Protonolysis takes place in aqueous solution, the rate increasing rapidly with increasing temperature and decreasing pH [1]. These solutions become more stable with increasing concentration of sodium borohydride. At 24 °C, a 10^{-2} M solution (pH = 9.56) decomposes to the extent of 15 % in 1 h, whereas a 0.10 M solution (pH = 10.05) undergoes only 5 % decomposition in the same time. On boiling or on acidification, however, rapid hydrolysis occurs and all the combined hydrogen is released (2.36 L/g at STP). A number of transition metal salts and finely divided metals such as nickel, cobalt, iron, and copper [1,46] catalyze the hydrolysis, but the addition of strong bases such as NaOH can stabilize solutions of $NaBH_4$ (Fig. 5).

Figure 4. Solubility of sodium borohydride in water as a function of temperature
The transition temperature is 36.4 °C.

Figure 5. Stability of sodium borohydride in alkaline solution (0.1 M $NaBH_4$, 24 °C)
a) 1.0 M NaOH; b) 0.25 M NaOH; c) 0.10 M NaOH.

A solution of sodium borohydride in concentrated sodium hydroxide can be stored virtually without decomposition, although concentrated solutions of sodium borohydride in dimethylformamide must not be heated because of the danger of explosion caused by autocatalytic decompositions; such solutions should not even be stored for long periods at room temperature [47]. Contact with strong acid (e.g., concentrated sulfuric or phosphoric acid, or methanesulfonic acid) or Lewis acids must be avoided as these substances can liberate diborane, which is highly toxic and spontaneously flammable.

Sodium borohydride is a powerful reducing agent with wide applications in inorganic and particularly organic chemistry. The redox potential E^0 of the half reaction

$$BH_4^- + 8\,OH^- \longrightarrow B(OH)_4^- + 4\,H_2O + 8\,e^-$$

at pH 14 is − 1.24 V.

An aqueous solution of sodium borohydride will reduce a number of cations and anions, the product obtained depending on the nature of the ion and the reaction conditions. A metal ion of lower valency can be produced (e.g., iron(II) from iron(III)), a metal (e.g., all the platinum metals, cadmium, mercury, lead, silver, and gold), a metallic boride (CrB_2, Co_2B, Ni_2B), or a hydride (GeH_4, SnH_4, AsH_3, BiH_3). Many of these reductions are used for the recovery of noble metals, the precipitation of toxic metals from water, the preparation of finely divided metals, and the electroless deposition of metals and metallic borides onto metallic and nonmetallic substrates [48, 49].

Another reaction of industrial importance is the reduction of sulfur dioxide or sodium hydrogen sulfite to sodium dithionite:

$$NaBH_4 + 8\,NaOH + 8\,SO_2 \longrightarrow 4\,Na_2S_2O_4 + NaBO_2 + 6\,H_2O$$

The reducing power of sodium borohydride towards some important functional groups is shown in Table 3. This reveals that $NaBH_4$ is a milder but also more selective reducing agent than $NaAlH_4$, allowing the reduction of aldehydes, ketones, acid chlorides, and imines in the presence of esters, epoxides, amides, nitriles, or nitro groups. Much research has been undertaken with the object of varying the reducing power over a wide range [50], e.g., by mixing sodium borohydride with metal salts ($Pd(NO_3)_2$, $AlCl_3$, $CoCl_2$, $NiCl_2$), thiols (e.g., ethanedithiol), or carboxylic acids (e.g., acetic acid, trifluoroacetic acid), by using different solvents (e.g., aprotic solvents or solvent mixtures) [51], or by using phase transfer catalysts [52].

A solution of $NaBH_4 - TiCl_4$ (ca. 3 : 1) in 1,2-dimethoxyethane reduces carboxylic acids to alcohols and nitro compounds to amines. The $NaBH_4 - CoCl_2$ system dissolved in lower alcohols or dioxane is also effective for these reductions, as well as the reduction of sulfoxides to sulfides and the hydrogenation of alkenes. Lithium chloride and sodium borohydride dissolved in diethylene glycol dimethyl ether form the intermediate $LiBH_4$ which, unlike $NaBH_4$, can reduce esters and epoxides. Sodium triacetoxyborohydride, $NaBH(OAc)_3$, produced in situ from $NaBH_4$ and three equivalents of acetic acid, exhibits such a weakening of reducing power that aldehydes are selectively reduced without ketones being affected [53]. Sodium borohydride and boron trifluoride in diglyme or THF yield diborane:

$$3\,NaBH_4 + 4\,BF_3 \cdot OEt_2 \longrightarrow 2\,B_2H_6 + 3\,NaBF_4 + 4\,Et_2O$$

Diborane is used mainly for hydroboration, but also acts as a strong electrophilic reducing agent, reducing carboxylic acids and nitriles but not acyl chlorides or nitro groups [54].

Sodium borohydride is also an important starting material for the production of tetrahydridoborates (borohydrides) of other metals, and of boranes and organoboron compounds, their derivatives and adducts [1]. Some examples of practical importance are:

$$MX_n + n\,NaBH_4 \longrightarrow M(BH_4)_n + n\,NaX$$

MX_n = LiCl, KOH, NR_4OH, $CaCl_2$, $ZnCl_2$, etc.

$$ML_mX_n \xrightarrow{NaBH_4} ML_mH_yX_{n-y}$$

M = Cr, Fe, Co, Ni, Rh, Pt, etc.; L = PPh_3, X = Cl, Br

$$NaBH_4 + (R_2NH_2)Cl \longrightarrow R_2NH \cdot BH_3 + NaCl + H_2$$

Production. Since the discovery of sodium borohydride in 1942 by H. J. Schlesinger, H. C. Brown, H. R. Hoeckstra, and L. R. Rapp [55], over 100 methods of preparation have been described, but few of these have achieved any practical significance. Industrial production in the United States started

in 1954 using the Schlesinger process [56], in which trimethyl borate reacts with an extremly fine dispersion of sodium hydride in a high boiling hydrocarbon oil at 250 – 280 °C and atmospheric pressure:

$$4\,NaH + B(OCH_3)_3 \longrightarrow NaBH_4 + 3\,NaOCH_3$$

Water is then added, causing separation of the hydrocarbon oil, which is recirculated. The aqueous phase contains the $NaBH_4$ together with caustic soda and methanol formed by hydrolysis of $NaOCH_3$. The methanol is recovered by distillation and used again for production of trimethyl borate. The product solution contains 12 % $NaBH_4$ and 42 % NaOH ($\varrho = 1.4\,g/cm^3$; $\eta_{23} = 79\,mPa \cdot s$) and is sometimes marketed as Sodium Borohydride – SWS by Ventron or alkaline aqueous solution by Nokia. Solid sodium borohydride is obtained from the alkaline aqueous solution by extraction with isopropylamine; the yield is better than 90 %.

A process developed by Bayer [57] (see Fig. 6) uses finely ground borosilicate glass, sodium, and hydrogen:

$$Na_2B_4O_7 \cdot 7\,SiO_2 + 16\,Na + 8\,H_2 \longrightarrow 4\,NaBH_4 + 7\,Na_2SiO_3$$

The borosilicate $Na_2B_4O_7 \cdot 7\,SiO_2$ is produced by fusion of borax and silica. The borosilicate is cooled, ground, and then reacted with sodium in an atmosphere of hydrogen at 300 kPa and 400 – 500 °C in a partly heterogeneous reaction. The sodium borohydride is extracted from the borohydride – silicate mixture with liquid ammonia under pressure. The yield is in excess of 90 %. Other processes are described in Refs. [1,5], and [57].

Commercial sodium borohydride is in powder – lump form (bulk density 0.4 – 0.5 kg/L), the purity being typically 98 % (Bayer, Chemetall, Ventron).

Analysis. Two main methods are used for the analysis of sodium borohydride: one gas volumetric and the other titrimetric. In the first of these, the sodium borohydride is reacted with acid and the evolved hydrogen measured. The second method is equally straightforward and requires no special analytical equipment. The sodium borohydride is converted to metaborate by reaction with excess oxidizing agent such as sodium hypochlorite or potassium iodate:

$$NaBH_4 + 4\,NaOCl \longrightarrow NaBO_2 + 4\,NaCl + 2\,H_2O$$

The excess oxidizing agent is determined by iodometric back-titration [48,49].

Figure 6. Flow diagram for production of sodium borohydride (Bayer process)
a) Borax reservoir; b) Quartz sand container; c) Oven; d) Quenching trough; e) Grinder; f) Borosilicate glass container; g) Reactor; h) Extractor; i) Drier.

Uses. The present annual consumption of sodium borohydride is estimated to be 2000–3000 t, mainly in the form of the 12 % solution. This means that it is by far the most important commercially available complex hydride. The largest amount is used in the paper and pulp industries, mainly in the United States and Scandinavia. The 12 % solution (Ventron, Nokia) is used for the in situ production of sodium dithionite, which is used to bleach wood pulp. Both sodium dithionite (made from sodium borohydride and sulfur dioxide) and sodium borohydride itself are used for reducing vat dyes to the leuco bases [58]. A patent claims that the reaction with sulfur dioxide can be used for the purification of exhaust gases from power stations burning fossil fuel [59].

Solid sodium borohydride is used as a reducing agent in the organic chemical and pharmaceutical industries, and although the quantities used for this purpose are considerably smaller than the demands of the paper industry, the selective reduction of aldehydes and ketones has become of major importance [24]. One of the biggest uses is in the stereoselective reduction of steroid ketones. Another is the synthesis of antibiotics such as chloramphenicol, dihydrostreptomycin, and thiophenicol, and also vitamin A. Other examples are reduction in the synthesis of prostaglandins, atropine, scopolamine, and flavorings and aromas.

Sodium borohydride is also used for cleaning and stabilization of process streams of many organic products. It chemically reduces harmful impurities such as aldehydes, ketones and peroxides, thereby improving color, odor, and the stability of the products towards heat, light, and oxidation. The technique is used in the production and subsequent treatment of epoxides, alcohols, amines, ethers, esters, carboxylic acids, alkenes, polymers [58], and paper [60]. The reduction of metal cations already mentioned is used on a large scale for the electroless deposition of metals and metal borides onto metals and other materials such as glass, ceramics, and plastics (“ Nibodur 1098” – Bayer [61], for the recovery of mercury from wastewater from the chlor-alkali electrolytic process (Ventron process, Koertrol) of lead from lead tetraalkyl production, and of silver and cadmium from spent photographic developing solutions [62, 63]. Finely disperse metals of the iron group for high quality magnetic tapes are produced by sodium borohydride reduction [58, 64]. Nickel boride and cobalt boride obtained by the reduction of the appropriate salt solutions are used as catalysts in gas- and liquid-phase reduction [58]. One final application for sodium borohydride depends on its ability to generate hydrogen gas: it is used as a foaming agent for organic polymers and inorganic construction materials [58, 65].

3.5. Sodium Cyanotrihydridoborate

Properties (see also Table 2). Sodium cyanotrihydridoborate, sodium cyanoborohydride, sodium cyanoboranate, $NaBH_3CN$, is a white, amorphous powder, melting with decomposition at 240–242 °C. Contact with the atmosphere must be avoided as it is extremely hygroscopic. It is very soluble in polar, especially protic, solvents such as water, alcohols, amines, and THF, but not in diethyl ether or hydrocarbons [66].

Production. Sodium cyanoborohydride can be prepared by reaction of sodium borohydride with anhydrous hydrogen cyanide with liberation of hydrogen. The use of free hydrogen cyanide can be avoided by reaction of $BH_3 \cdot THF$ (formed in situ from BF_3 and $NaBH_4$) with sodium cyanide in suspension in THF [67]. The yield is 59–71 %:

$$BH_3 \cdot THF + NaCN \longrightarrow NaBH_3CN + THF$$

Another method is the reaction of $NaBH_4$ with $Hg(CN)_2$ [68]. The commercial product contains 95 % $NaBH_3CN$ (Aldrich, Ventron).

Uses. Sodium cyanoborohydride is used as a selective reducing agent in the synthesis of pharmaceuticals. Its special reducing properties (see Table 3) arise from its remarkable resistance to hydrolysis. It is stable even at pH 3 in water and methanol, its rate of hydrolysis being slower than that of $NaBH_4$ by a factor of 10^8 [66]. Reactivity and stereoselectivity are considerably affected by the nature and acidity of the solvent. In polar aprotic solvents such as hexamethylphosphoric triamide (HMPT) or dimethyl sulfoxide (DMSO) it reduces aliphatic halides and toluenesulfonates to the corresponding hydrocarbons. Under these conditions other

reducible functional groups such as epoxides, ketones, and aldehydes are unaffected. In combination with ZnI_2, sodium cyanoborohydride deoxygenates certain aldehydes and ketones under very mild conditions (20 h at room temperature in dichloromethane) [69].

In protic solvents, preferably at pH 3 – 4, carbonyl compounds and derivatives such as oximes and imines can be reduced. At pH 6 the reaction with carbonyl groups practically ceases, whereas imines are reduced smoothly. This is a good method for the reductive amination of a ketone or aldehyde in the presence of an amine [70]. Because of its resistance to hydrolysis, sodium cyanoborohydride is used for the chemical precipitation of metals from neutral or even acidic solutions of their salts (e.g., those of Ni, Co, Cr, Cd, Cu, and Ag) [71].

3.6. Potassium Tetrahydridoborate

Properties (see also Table 2). Potassium tetrahydroborate, potassium borohydride, potassium boranate, KBH_4, is a white salt that is completely stable in dry air. It is not hygroscopic and hydrolyzes only extremely slowly in moist air (1.7 % in 48 d). Potassium borohydride is thermally more stable than the sodium salt, but is generally much less soluble (see Table 4).

Potassium borohydride ignites in air above 300 °C. It decomposes slowly at 500 °C in vacuum . In a hydrogen atmosphere it melts at ca. 585 °C. Aqueous solutions are relatively stable, but decompose completely on boiling, liberating hydrogen (1 g of KBH_4 liberates 1.66 L of H_2 at STP). The addition of alkali renders the solution stable up to 100 °C [1].

Production. Potassium borohydride is produced on an industrial scale by a metathetical reaction of sodium borohydride:

$$NaBH_4 + KOH \longrightarrow KBH_4 + NaOH$$

A methanol – water solution of sodium borohydride is treated with a stoichiometric amount of aqueous potassium hydroxide. The precipitated potassium borohydride is centrifuged, washed, and dried under vacuum [72]. The commercial product is a crystalline powder with a purity of 98 % (Goerrig-Chemie, Ventron).

Uses. Potassium borohydride is used to a limited extent as a selective reducing agent in preparative organic chemistry. Its reducing power is only slightly weaker than that of sodium borohydride.

3.7. Aluminum Hydride

Aluminum hydride [*7784-21-6*], alane, AlH_3, is a colorless, nonvolatile substance that exists as a polymer with Al – H – Al 3-center, 2-electron bonds. It is produced by reaction of lithium aluminum hydride with aluminum chloride or acid in diethyl ether [3]:

$$3\,LiAlH_4 + AlCl_3 \longrightarrow 4\,AlH_3 + 3\,LiCl$$

$$LiAlH_4 + HX \longrightarrow AlH_3 + LiX + H_2$$

$$HX = HCl,\ H_2SO_4$$

Monomeric alane etherate solution is first formed, which soon polymerizes, but the polyalane produced still contains ether, which cannot be removed even by heating under high vacuum. A solvent-free product may be obtained by reaction with excess lithium aluminum hydride [73]. Ether-containing products are decomposed by contact with water or by heating to 80 – 90 °C, but the ether-free products are more stable.

Aluminum hydride is a rather milder reducing agent than lithium aluminum hydride. It has been proposed for a large number of applications, including rocket fuel and for coating objects with a thin layer of aluminum; nevertheless, it is not commercially available. Many adducts and derivatives of aluminum hydride are known of which two have been employed industrially: polyiminoalanes are used as cocatalysts in the stereospecific polymerization of isoprene [74], and diisobutylaluminum hydride [*1191-15-7*] is used as a reducing agent [75] (Schering AG, Ethyl Corporation, Texas Alkyls) (→ Aluminum Compounds, Organic). The production of amine – alane complexes in hydrocarbons has been reported [76].

3.8. Lithium Tetrahydridoaluminate

Properties (see also Table 2). Lithium tetrahydridoaluminate, lithium aluminum hy-

dride, lithium alanate, $LiAlH_4$, is a fine crystalline powder. It is stable in the absence of moisture, but after some months at room temperature it becomes gray due to traces of elemental aluminum. This extremely slow decomposition hardly affects the reactivity of the product. On heating in the absence of air, decomposition starts at 125 °C with liberation of hydrogen. The first product is Li_3AlH_6, which itself decomposes above 200 °C into LiH, Ae, and H_2; the ultimate decomposition products are LiAl and H_2 (430 °C) [77]. If $LiAlH_4$ is heated in air, the liberated hydrogen ignites and burns quietly, and the metallic residue then burns with incandescence, whereby nitrogen also takes part in the reaction (see Chapter 6 for fire precautions). Moist air causes $LiAlH_4$ to lose reactivity as a result of hydrolysis, but under normal conditions it is not spontaneously flammable. It reacts extremely violently with water. The liberated hydrogen (2.3 L/g at STP) usually ignites spontaneously because of the large heat of hydrolysis ($\Delta H^0_{298} = -714$ kJ/mol).

Lithium aluminum hydride is soluble in various ethers (see Table 5), but not in hydrocarbons. It forms very stable solvates with some ethers and with tertiary amines; these solvates can very often be isolated. Some solvates are soluble in hydrocarbons. The solvate containing 1.6 mol of THF per mole of lithium aluminum hydride dissolves in toluene to form a 1.1 M lithium aluminum hydride solution [78]. The chelate complexes with tertiary polyamines are also soluble in hydrocarbons [79]. Solutions of $LiAlH_4$ are usually cloudy due to the presence of traces of insoluble oxygen-containing compounds and other byproducts that arise during production. Nevertheless, quality is not affected.

Concentrated solutions of $LiAlH_4$ are most conveniently obtained by the concentration of dilute solutions rather than by dissolving the solid compound, as the rate of dissolution is low. All operations with $LiAlH_4$ should be carried out in an inert atmosphere.

Lithium aluminum hydride is a powerful nucleophilic reducing agent. It reduces almost all functional groups (see Table 3), although isolated double and triple bonds in alkenes and alkynes are generally not attacked. There is a very extensive literature on the subject of $LiAlH_4$ reductions; for monographs and reviews, see [5,23,39,80,81]. A typical reaction is the reduction of a carboxylic acid:

$$4\,R{-}COOH + 3\,LiAlH_4 \longrightarrow (R{-}CH_2O)_4AlLi + 2\,LiAlO_2 + 4\,H_2$$

$$(R{-}CH_2O)_4AlLi + 4\,H_2O \longrightarrow 4\,R{-}CH_2OH + LiAl(OH)_4$$

One hydride equivalent is required for reaction with the acidic hydrogen atom and two further equivalents for the reduction of the carbonyl group. Essentially three methods are available for the hydrolysis of the aluminate complex and of the excess hydride [78]:

1) Hydrolysis with the theoretical amount of water (4 mol water per mole of $LiAlH_4$). The byproduct $LiAl(OH)_4$ precipitates and can be removed by centrifugation or filtration.
2) Hydrolysis with an excess of water (10–20 mol H_2O per mole $LiAlH_4$) and addition of sodium hydroxide or potassium carbonate solution [82]; the hydroxides form a granular or gelatinous precipitate. The product solution can then be decanted or siphoned off.
3) Hydrolysis with dilute mineral acid. The hydroxides dissolve and form an aqueous phase that can easily be separated from the organic phase.

The optimum hydrolysis conditions depend on the substrate and should be established in the laboratory for each reduction.

The powerful reducing action and consequent poor selectivity of $LiAlH_4$ can be modified by means of various additives. The addition of different amounts of $AlCl_3$ leads to the formation of the electrophilic chloroalanes and AlH_3, e.g.,

$$LiAlH_4 + AlCl_3 \longrightarrow 2\,AlH_2Cl + LiCl$$

These are milder and therefore more selective reducing agents than pure $LiAlH_4$ [5,81]. Nevertheless, chloroalanes encourage hydrogenolysis because of their electrophilic character. Thus, under certain conditions, ketones, carboxylic acids, esters, and alcohols can be converted into hydrocarbons. Reduction with mixtures of $LiAlH_4$ and $AlCl_3$ must be carried out in diethyl ether because THF is cleaved by this reagent.

The reducing power of $LiAlH_4$ can also be modified by the introduction of alkoxy substituents [5,81,83]:

$$LiAlH_4 + n\,ROH \longrightarrow LiAlH_{4-n}(OR)_n + n\,H_2$$

The alkoxyalanates so obtained are considerably more selective than $LiAlH_4$, and are able, for example, to reduce keto groups without reducing ester groups also present in the molecule. Alkoxyalanates can be prepared in situ; lithium (tri-*tert*-butoxy)hydridoaluminate (Section 3.9) is commercially available. Amines can also be used to modify the reducing properties of $LiAlH_4$. One example is the reduction of esters to aldehydes in the presence of diethylamine [84].

In the presence of chiral alcohols, amines, or aminoalcohols, prochiral ketones and aldehydes are reduced to optically active alcohols, often with very good selectivity [85]. The capacity for asymmetric reduction is mainly of interest for the pharmaceutical industry [86]. In the presence of catalytic quantities of $TiCl_4$, alkenes can be smoothly converted by $LiAlH_4$ to the corresponding alkanes [87, 88]. Hydroalumination is an alternative to hydroboration.

The reaction of $LiAlH_4$ with metal halides yields hydrides and the corresponding tetrahydroaluminates of the metals concerned [3, 38]. The preparation of transition metal tetrahydridoaluminate complexes using $LiAlH_4$ is described in a review [89].

Production. Lithium aluminum hydride was first synthesized in 1945 by FINHOLD, BOND, and SCHLESINGER [90]:

$$4\,LiH + AlCl_3 \longrightarrow LiAlH_4 + 3\,LiCl$$

The present industrial process uses this method. A solution of aluminum chloride in ether is slowly added to a suspension of finely divided lithium hydride containing some $LiAlH_4$. The heat of reaction keeps the mixture at its boiling point. After completion of the reaction, the lithium chloride and excess lithium hydride are filtered off and the ether is removed under reduced pressure. Only 25 % of the lithium is used to form the desired product. The economics can be improved by electrolysis of the lithium chloride byproduct to give lithium metal, which can be hydrogenated to lithium hydride, or used for other purposes (→ Lithium and Lithium Compounds).

Other preparative methods not used in industry are direct synthesis from lithium hydride, aluminum, and hydrogen under pressure in THF:

$$2\,LiH + 2\,Al + 3\,H_2 \longrightarrow 2\,LiAlH_4$$

and the metathetical reaction between sodium aluminum hydride and lithium chloride in diethyl ether [38]:

$$NaAlH_4 + LiCl \longrightarrow LiAlH_4 + NaCl$$

The usual commercial product (Chemetall, Ventron) is typically 97 % $LiAlH_4$. For ease of handling it is also supplied in tablet form or in bags that are soluble in diethyl ether, THF, or toluene [78]. Ready-to-use $LiAlH_4$ solutions are also available for industrial scale reductions, e.g., 10 % in THF, 20 % in diethyl ether, and 15 % as the THF complex in toluene [78]. The solutions are supplied in containers with dip tubes so that they can be transferred to reaction vessels without coming into contact with the atmosphere.

Analysis [78]. The analysis of solid $LiAlH_4$ is best carried out by the gas volumetric method. A weighed sample is cautiously hydrolyzed in a mixture of dioxane and water and the volume of hydrogen released is measured. Solutions of $LiAlH_4$ are conveniently analyzed by titration (Felkin's method [78]). The $LiAlH_4$ is reacted with an excess of iodine which is then back-titrated with sodium thiosulfate.

$$LiAlH_4 + 2\,I_2 \longrightarrow 2\,H_2 + LiAlI_4$$

Uses. Bulk lithium aluminum hydride is used almost exclusively for the reduction of organic functional groups. The principal consumers are the organic chemical, pharmaceutical, and the flavoring and perfumery industries. Lithium aluminum hydride is more expensive than sodium borohydride and is mainly used when the reducing power of the latter is inadequate.

Lithium aluminum hydride is used in industry mainly for the reduction of carboxylic acids and esters to alcohols, and of amides, imides, and nitriles to amines. Its powerful reducing properties are also used in the reduction of sterically hindered compounds. It has the advantage over some other reducing agents of being very clean to use as the precipitated sludges from the hydrolysis of the aluminate complex are easily separated and there are no toxic or gaseous byproducts. Furthermore, it has the highest hydrogen

content per unit mass of the commercially available complex hydrides. Lithium aluminum deuteride, $LiAlD_4$ [*14128-54-2*] (Chemetall), is also commercially available and is used for isotopic labelling of organic compounds with deuterium.

3.9. Lithium (tri-tert-butoxy)hydridoaluminate

Properties (see also Table 2). Lithium (tri-*tert*-butoxy)hydridoaluminate, $LiAlH[OC(CH_3)_3]_3$, is a white powder that sublimes at 280 °C and 200 Pa, and melts with decomposition at 319 °C. Its high thermal stability is consistent with its milder reducing properties compared with $LiAlH_4$ [83]. It can be handled in air without danger but is slowly hydrolyzed, thereby losing activity. Solubility data are given in Table 5. Lithium (tri-*tert*-butoxy)hydridoaluminate is produced by the reaction of $LiAlH_4$ with *tert*-butanol in ether solution:

$$LiAlH_4 + 3\,(CH_3)_3COH \longrightarrow LiAlH[OC(CH_3)_3]_3 + 3\,H_2$$

The commercial product has a typical purity of 98 % (Chemetall).

It is very suitable for selective reductions on account of its mild reducing power (see Table 3), the most important of these being the reduction of steroid ketones [23]. In addition to chemical selectivity, a certain stereoselectivity is shown in the reduction of cyclic ketones.

3.10. Sodium Tetrahydridoaluminate

Properties (see also Table 2). Sodium tetrahydridoaluminate, sodium aluminum hydride, sodium alanate, $NaAlH_4$, is a white, crystalline substance, *mp* 178 °C; it decomposes at 210 °C, liberating hydrogen and initially forming Na_3AlH_6 [77]. Sodium tetrahydridoaluminate is insoluble in hydrocarbons and diethyl ether. Its chemical properties resemble those of lithium aluminum hydride. However, the strong polar character of sodium aluminum hydride promotes side reactions during some reductions [5].

Production. Sodium aluminum hydride can be produced by reaction of sodium hydride with aluminum chloride in THF [91]:

$$4\,NaH + AlCl_3 \longrightarrow NaAlH_4 + 3\,NaCl$$

A more economical method is the direct synthesis from the elements:

$$Na + Al + 2\,H_2 \longrightarrow NaAlH_4$$

The reaction is carried out at elevated temperature (100 – 200 °C) and pressure (10 – 20 MPa) preferably in hydrocarbon solvent. The presence of a catalyst such as triethyl aluminum is necessary [92–94]. Sodium aluminum hydride is supplied as a laboratory reagent by Ethyl Corporation; however, it has not yet been produced on an industrial scale.

3.11. Sodium bis(2-methoxyethoxy)dihydridoaluminate

Properties [95] (see also Table 2). Sodium [bis(2-methoxyethoxy)]dihydridoaluminate (SDMA), $NaAlH_2(OCH_2CH_2OCH_3)_2$, is a colorless, viscous liquid at room temperature that solidifies to a glass below 0 °C; there is no sharp melting point. It is stable up to 170 °C and decomposes above 214 °C. At higher temperature decomposition is sudden and spontaneous.

The presence of the two methoxyethoxy groups confers solubility not only in ethers but also in aromatic hydrocarbons. It is completely miscible with toluene at concentrations below 6 % and above 42 %. Viscous solutions of SDMA can be handled in contact with air, although atmospheric moisture causes hydrolysis.

The reducing properties of SDMA are comparable with those of $LiAlH_4$ (see Table 3). For example, the reaction with aldehydes takes place as follows:

$$2\,R-CHO + NaAlH_2(OCH_2CH_2OCH_3)_2 \longrightarrow NaAl(R-CH_2O)_2(OCH_2CH_2OCH_3)_2 \xrightarrow{H_2O} 2\,R-CH_2OH + 2\,HOCH_2CH_2OCH_3 + NaAl(OH)_4$$

The complex aluminate intermediate is often soluble, so that the reduction takes place in a homogeneous phase and usually gives good yields. Hydrolysis can be carried out with acid or base. Most of the 2-methoxyethanol

[*109-86-4*] formed dissolves in the aqueous phase. 2-Methoxyethanol has a harmful effect on the central nervous system (MAK 5 ppm). In comparison to reductions with $LiAlH_4$, twice the amount of unwanted precipitate (sodium aluminum hydroxide) is formed, which can trap some of the reduced product and make work-up more difficult.

Production. One method of preparation is the controlled alcoholysis of $NaAlH_4$ with 2-methoxyethanol:

$$NaAlH_4 + 2\,CH_3OCH_2CH_2OH \longrightarrow NaAlH_2(OCH_2CH_2OCH_3)_2 + H_2$$

On an industrial scale, however, it is produced by direct synthesis from sodium, aluminum, and 2-methoxyethanol at 140 – 155 °C in an atmosphere of hydrogen at at least 7 MPa:

$$Na + Al + 2\,CH_3OCH_2CH_2OH \longrightarrow NaAlH_2(OCH_2CH_2OCH_3)_2$$

The quantity of hydrogen required is generated in situ by the reaction of sodium and aluminum with the alcohol. SDMA is marketed as a 70 % solution in toluene ($\varrho = 1.036$ g/cm^3) under the name Vitride (Hexcel).

Uses. The most important application of SDMA is as a reducing agent in the production of fine chemicals, but it is also used as a catalyst for the polymerization of lactams and alkenes, and for the trimerization of organic isocyanates. The use of SDMA as an activator in the preparation of Grignard reagents has been described [96].

3.12. Sodium Diethyldihydridoaluminate

Properties (see also Table 3). Sodium diethyldihydridoaluminate, $NaAlH_2(C_2H_5)_2$, is a white, crystalline substance, *mp* 85 – 87 °C, which ignites spontaneously in air. It is insoluble in aliphatic but fairly soluble in aromatic hydrocarbon solvents. The solubility of sodium diethyldihydridoaluminate in toluene can be considerably increased by addition of a small amount of THF. Solutions of this reagent must be kept under an inert atmosphere, since they lose their activity by hydrolysis and oxidation if exposed to air. The reducing power of this hydride is comparable with that of $LiAlH_4$ (see Table 3). The ethyl groups generally do not take part in the reduction, but give rise to large volumes of ethane when the intermediate aluminate complex is hydrolyzed. This ethane should be safely disposed of, preferably by burning.

Production. Sodium diethyldihydridoaluminate is produced by reaction of sodium, aluminum, and triethyl aluminum in toluene at ca. 150 °C and 7 MPa hydrogen pressure.

$$3\,Na + Al + 2\,Al(C_2H_5)_3 + 3\,H_2 \longrightarrow 3\,NaAlH_2(C_2H_5)_3$$

Improved yields and reduced reaction times are obtained by the addition of small amounts of the final product as a catalyst, and by splitting the process up into several stages [97]. Until 1987 the product was marketed in industrial quantities as a 25 % solution under the name OMH-1 (Ethyl Corp.).

The solubility of alkali metal dialkyldihydridoaluminates in aromatic hydrocarbons can be markedly increased if the two alkyl groups are different [98]. Thus, a 40 % solution of sodium butylethyldihydridoaluminate, $NaAlH_2(C_2H_5)_{1.5}(n\text{-}C_4H_9)_{0.5}$, is available in pilot-plant quantities (Schering).

4. Recommended Techniques for Working with Hydrides

It is quite possible to work with hydrides on an industrial scale without any problems provided that certain safety aspects of plant design are borne in mind [78, 99].

Almost all the binary and complex hydrides described here are highly reactive towards water, and therefore any possibility of accidental contact, e.g., by failure of a water-cooled reflux condenser, must be strictly avoided. If it is not possible to use inert coolants (such as mineral oil or decalin), pressure-tested metal reflux condensers must be installed, and the use of automatic water alarm systems is recommended.

All hydrides are sensitive to air and moisture to a greater or lesser extent, and they must therefore be handled in an inert atmosphere such as nitrogen or argon. By using such an atmosphere throughout the whole production plant,

Figure 7. Inert gas breathing system recommended for working with metal hydrides

the risk of formation of explosive hydrogen – air mixtures, e.g., from the hydrolysis of reducing agents, can be largely avoided. A scheme for an inert gas breathing system in which all parts of the equipment are linked together is shown in Figure 7. Each vessel is connected by a pipeline to the breather manifold (a), which is connected via a buffer vessel and an efficient reflux condenser (c) to the breather regulator (f). The reflux condenser should be operated at as low a temperature as possible, to recover as much solvent vapor as possible from the inert gas, thereby minimizing emissions. In addition to the inert gas breathing system, a safety vent system (b) is provided. This is constructed in a similar way. All breathing and safety pipelines enter the common lines from above to prevent solvent carryover or possible transfer of product into other vessels by foaming.

Since flammable solvents are usually used in reduction and metallation reactions, the entire production area must be well ventilated to prevent the accumulation of solvent vapor – air mixtures; electrical installations must be explosion-proof.

A typical flow diagram for reductions with complex hydrides is shown in Figure 8 (see next page). The arrows show the route for a normal reduction procedure, i.e., that in which the substrate solution is passed into a solution of the reducing agent. If inverse addition is required, the reactor (b) can be used for dissolving the hydride. The hydrolysis of the intermediate complex need not be carried out in the hydrolyzer (c); it can be done in the reactor. However, the latter must be carefully dried before each new addition of reactants.

5. Hydrides of the Transition Metals

5.1. Binary Hydrides

Hydrogen reacts at elevated temperature with many transition metals and their alloys to form hydrides. The electropositive elements are the most reactive, i.e., scandium, yttrium, the lanthanides, the actinides, and the members of the titanium and vanadium groups. In contrast to the ionic hydrides, the binary hydrides of the transition metals are predominantly metallic in character and are usually referred to as metallic hydrides. They are good conductors of electricity, possess a metallic or graphite-like appearance, and can often be wetted by mercury. Many of these compounds (MH_n) show large deviations from ideal stoichiometry ($n = 1, 2, 3, \ldots$) and can exist as multi-phase systems. The lattice structure is that of a typical metal with atoms of hydrogen embedded in it; for this reason they are also called interstitial hydrides.

This type of structure has the limiting compositions MH, MH_2, and MH_3; the hydrogen atoms fit into octahedral or tetrahedral holes in the metal lattice, or a combination of the two types. The hydrogen carries a partial negative charge, depending on the metal (an exception is, for example, $PdH_{0.7}$) [100].

Only a small number of the transition metals are without known stable hydrides. The elements of group 3 (scandium, yttrium, actinium),

Figure 8. Simplified flow diagram for reductions with metal hydrides
a) Metering vessel; b) Reactor; c) Hydrolysis vessel; d) Evaporator; e) Filter or centrifuge.

the lanthanides, and the actinides have electronegativities comparable with those of the alkaline earths, and all react exothermically with hydrogen to form stable (defect) "dihydrides," which can mostly be converted into "trihydrides." The metals of group 4 (titanium, zirconium, hafnium) all form stoichiometric dihydrides whose enthalpies of formation are as high as those of the alkaline earth metal hydrides. Of the metals of group 5, vanadium and niobium are known to form mono- and dihydrides, while tantalum forms only a hydride of the limiting formula $TaH_{0.9}$. A considerable "hydride gap" exists in the periodic table, beginning at group 6, in which the only hydrides are palladium hydride ($PdH_{0.7}$), the very unstable nickel hydride ($NiH_{0.7}$), and the poorly defined hydrides of chromium (CrH, $CrH_{1.8}$) and copper (CuH). Nevertheless, there are many known complex-stabilized hydrides of these elements (see Section 5.3). In palladium hydride, the hydrogen has high mobility and probably a very low charge density. In the finely disperse state, platinum and ruthenium are able to adsorb considerable quantities of hydrogen, which thereby becomes activated. These two elements, together with palladium and nickel, are extremely good hydrogenation catalysts, although they do not form hydrides [4].

One of the most interesting features of the metallic hydrides is the extremely high density of the hydrogen atoms present. This is higher than it is in liquid hydrogen, e.g., in ZrH_2 by 70 %, in UH_3 by 93 %, and in TiH_2 by as much as 113 %. These compounds (e.g., TiH_2 and ZrH_2) have attracted great interest in the nuclear industry because hydrogen is a very powerful neutron moderator and because some metallic hydrides are both chemically stable and mechanically strong. According to the neutron absorption cross section of the metals, they can be suitable for use as moderators, reflectors, or shielding materials [4]. In the metallurgical industry, hydrogenation of the metals of groups 3, 4, and 5, and of thorium and uranium is used in metal powder production and in processing scrap metal. Hydrogen treatment reduces the density, ductility, and toughness, facilitating mechanical size reduction. After grinding, the product is degasified under vacuum, yielding a

powdered metal that is easily sintered and generally suitable for powder metallurgy [101].

5.1.1. Titanium Hydride

Properties (see also Table 6). The stoichiometric dihydride $TiH_{2.00}$ has a metallic appearance and crystallizes in a face-centered cubic structure of the fluorite type, which changes to a tetragonal structure below room temperature. The commercial product is a gray, finely divided powder with the composition $TiH_{1.95}$. The titanium – hydrogen system has been described in detail [102, 103]. One phase of the formula $TiH_{1.38}$ represents the most stable composition. The eutectic between α-Ti and TiH_2 (γ-phase) melts at 300 °C and contains ca. 38 atom% hydrogen. At atmospheric pressure, TiH_2 slowly loses hydrogen at ca. 350 °C. About 8 % of the theoretical hydrogen content is lost at 500 °C, 15 % at 600 °C, and 62 % at 800 °C. Only at the melting point of titanium (1668 °C) is the dissociation virtually complete. Titanium hydride possesses chemical resistance similar to that of the metal. At room temperature titanium hydride is completely unaffected by air and water. It is slowly attacked by most strong acids, but is readily soluble in hydrofluoric and hot sulfuric acids.

Table 6. Physical data for transition metal hydrides

Formula	CAS registry number	M_r	Density, g/mL	$H_{B\,(298)}$, kJ/mol
TiH_2	[*7704-98-5*]	49.92	3.76	− 124
ZrH_2	[*7704-99-6*]	93.24	5.61	− 163
Cp_2ZrHCl	[*37342-97-5*]	257.87		
$HRhCO(PPh_3)_3$	[*17185-29-4*]	918.81		

Titanium hydride reacts with oxidizing agents extremely vigorously, especially in a finely disperse state at elevated temperature; it ignites readily, and is therefore used in pyrotechnic mixtures. Dust explosions are possible. Powdered titanium hydride can be handled in air at room temperature and atmospheric pressure without danger; is is less sensitive than titanium powder of similar particle size. Titanium hydride ignites when heated in air above 400 °C. First, the liberated hydrogen burns quietly, and then the titanium reacts to form the oxide and nitride with a bright incandescence. To prevent ignition by friction, titanium hydride should only be ground when wet or under an inert atmosphere.

Production. Titanium hydride is produced industrially by hydrogenation of titanium sponge at atmospheric pressure and 300 – 500 °C. The exothermic absorption of hydrogen begins above 200 °C, is very rapid at 400 – 500 °C, and is completed during cooling in the hydrogen atmosphere. The hydrogenated sponge is brittle and easily ground to a fine powder. The commercial product has a particle size of 5 µm and a bulk density of ca. 1.4 g/cm^3 (Degussa, Ventron). The product contains 94.5 – 95.5 % titanium, 3.8 – 4.0 % hydrogen, and 0.1 – 1.0 % oxygen. An even finer product is produced by the Hydrimet process, in which titanium dioxide is reduced with calcium hydride at 600 – 700 °C to form titanium metal. This is then hydrogenated in situ at 300 – 400 °C and the byproduct calcium oxide is removed by dissolution in dilute hydrochloric acid [104].

Uses. Titanium hydride is mainly used in the powder metallurgical industry to promote good pressing and sintering. It is added to powdered metals because during sintering it generates a protective hydrogen atmosphere, which reduces the oxide film on the metal surface, combines with and removes carbon, and increases the density of the sintered product. It is used as an additive (2 – 5 %) in the production of Alnico and Ticonal sintered magnets for high performance loudspeakers and for sintered boride materials [105]. Titanium metal powder is produced industrially by heating ground titanium hydride to 600 °C and applying a vacuum. When this reaches 10^{-3} Pa the hydrogen is completely removed. Titanium nitride in extremely finely divided form is produced by reaction with ammonia or ammonium halides at atmospheric pressure and 400 – 700 °C. Titanium nitride is used as an ultra-hard, heat-resistant material [106].

Titanium hydride can also be used to assist ceramic materials such as glass and porcelain to bond with each other or with metals [107]. On heating with the hydride, a strongly bonded coating of titanium is formed on the nonmetallic surface. This can then be bonded to metals using a solder (e.g., silver – copper).

Titanium hydride is also used for making metallic foams [108] and as a surface coating on titanium alloys for corrosion protection against

sea water or acidic solutions [109]. Investigations are continuing into the possible use of shielding materials containing titanium hydride for fusion reactors of the Tokamak type [110].

5.1.2. Zirconium Hydride

Properties (see also Table 6). At 300 °C, pure zirconium metal reversibly absorbs hydrogen until the stoichiometric dihydride $ZrH_{2.00}$ (ε-phase) is formed. This compound crystallizes in a body-centered tetragonal structure. The reaction takes place in several stages, forming the metastable γ-phase (ZrH), then the stable δ-phase ($ZrH_{1.59-1.67}$), and finally the ε-phase with the highest hydrogen content ($ZrH_{1.67-2.00}$). The eutectic is at 550 °C and 33 atom% H [4, 102]. Zirconium hydride is thermally more stable than titanium hydride. At atmospheric pressure, it dissociates at 500 °C. At 600 °C it has lost ca. 6 % of its theoretical hydrogen content, at 800 °C 19 %, and at 900 °C 50 %. Hydrogen-free zirconium powder is produced by the dehydrogenation of powdered ZrH_2 in vacuum (10^{-3} Pa) at 800 °C. The chemical properties of zirconium hydride and titanium hydride are very similar, although zirconium hydride is much more sensitive towards oxidizing agents. It is inert to air and water at room temperature. The usual commercial product, a grayish black powder with particle size 2 – 6 µm, ignites in air at ca. 250 – 300 °C. The hydride should therefore only be ground in an inert gas atmosphere (argon) or when wetted with water.

Production. Zirconium hydride that conforms to various quality requirements is produced either by direct hydrogenation of metallic zirconium or by the reduction of zirconium dioxide with calcium hydride, calcium, or magnesium in a hydrogen atmosphere (Degussa, Ventron).

Zirconium sponge is hydrogenated at 300 °C mainly for the production of the pure hydride with a low hafnium content for the nuclear industry (96.9 – 97.9 % zirconium, 1.9 – 2.1 % hydrogen, <0.01 % hafnium, ≤0.14 % other metals), and also for the production of zirconium metal powder for the powder metallurgical industry.

The reduction of purified ZrO_2 with calcium hydride yields a very fine, pure hydride powder (96.5 – 97.5 % zirconium, 1.9 % hydrogen; particle size 2 – 3 µm), which is quite suitable for most applications:

$$ZrO_2 + 2\,CaH_2 \longrightarrow ZrH_2 + 2\,CaO + H_2$$

Technical quality zirconium dioxide is reduced by calcium/magnesium in a hydrogen atmosphere to give a relatively cheap hydride powder quite suitable for use in pyrotechnics (91.5 – 93.5 % zirconium, 1.3 – 1.5 % hydrogen, particle size 2 – 3 µm).

Uses. Zirconium hydride is used in the nuclear industry as a moderator for thermal neutrons, especially in light water reactors and fast breeder reactors. It can be formed by warm pressing and is characterized by low neutron absorption and high thermal stability and mechanical strength [111]. Very effective shielding materials contain a combination of a neutron absorber (e.g., boron carbide or zirconium) with a moderator such as zirconium hydride [112]. Zirconium hydride is also widely used as a getter in vacuum and ultra-high vacuum technology, e.g., for pipework and electric lights; it is able to bind up to 40 % oxygen or up to 20 % nitrogen [113]. Like titanium hydride, zirconium hydride can provide a bond between nonmetallic materials (e.g., SiN and SiC) and metals. Zirconium hydride is added at a concentration of 0.01 – 5 % to a matrix of silver, copper, or nickel alloys to form reactive brazing compounds [114].

Zirconium hydride is a component of pyrotechnic formulations (with potassium chlorate as the oxygen source) for signal flares, tracer munition, or primer compositions. The burning properties are determined by grain size, specific surface, and particularly hydride content. Increasing hydrogen content leads to slower burning rates [115].

5.2. Intermetallic Hydrides

There is increasing interest in the broad field of the ternary system $M^1 - M^2 - H$ of intermetallic compounds or alloys of transition metals and hydrogen. These compounds can sometimes contain more hydrogen than would be expected from the absorption properties of the individual metal

components. The alloys with the greatest capacity for hydrogen are of the AB (e.g., FeTi or EuRu) or AB_5 type (e.g., $LaNi_5$ or $CaNi_5$) [116].

The thermochemical processes associated with absorption and desorption can be used for heat pumps and refrigeration systems (→ Hydrogen).

5.3. Complex Hydrides of Transition Metals

Transition metals form a large group of hydrides stabilized by complex formation: $H_xM_nX_yL_z$ (L = neutral ligand, X = anionic ligand, M = central metal atom). In these mono- or polynuclear complexes the hydrogen is linked by covalent bonds either to one metal atom, or it acts as a bridge between two centers (e.g., in many polynuclear complexes and in tetrahydroborate complexes). Further bonds with neutral or anionic ligands (less frequently with cationic ligands such as NO^+) enable most complexes to attain the electronic configuration of the next inert gas (the 18 electron rule). Rhenium and technetium are the only transition metals known to form hydrido complexes containing only hydride ligands, i.e., $[ReH_9]^{2-}$ and $[TcH_9]^{2-}$. Most transition-metal hydride complexes are stabilized by π-bonding ligands, e.g., tertiary phosphines and arsines (PR_3, AsR_3, respectively), the cyclopentadienyl anion ($C_5H_5^-$), and carbon monoxide.

The first hydrido complexes were discovered by Hieber [117] in the early 1930s; these were the unstable carbonyl hydrides of iron, $[H_2Fe(CO)_4]$, and cobalt, $[HCo(CO)_4]$. In the 1950s, research activity increased greatly and led to the discovery of hydrido complexes of all the d-elements [6].

Hydrido complexes of cobalt, nickel, ruthenium, rhodium, and iridium are industrially important homogeneous catalysts for many reactions of alkenes and alkynes. These catalysts are usually prepared in situ and are rarely used in the form of isolated complexes. For example, a number of rhodium complexes can be used in the hydrogenation of alkenes, especially $RhCl(PPh_3)_3$ (Wilkinson's catalyst). Hydrogen oxidatively adds to this complex giving a dihydrido complex which then hydrogenates the alkene:

The reaction mechanism has been studied in detail [118].

The first industrial application of a hydrido complex as an intermediate dates from 1940 when Ruhrchemie operated a cobalt-catalyzed hydroformylation process (the Oxo process) on an industrial scale [6, 118] (→ Oxo Synthesis; see also → Carbonylation). The cobalt catalyst, introduced as $Co_2(CO)_8$, is converted under the reaction conditions into tetracarbonylcobalt hydride, which then catalyzes the reaction between an alkene and CO to form aldehydes:

World output of C_3-C_{18} aldehydes by this method is ca. 100 000 t/a. Rhodium-catalyzed hydroformylation was developed in the mid 1970s, mainly by Union Carbide. The technical advantages include greater selectivity and conversion rate. The complex $HRh(CO)(PPh_3)_2$ is often used as catalyst [118, 119].

Complex hydrides are also important in isomerization, dimerization, and polymerization of dienes.

Stoichiometric reactions of metal hydrido complexes have also attained some importance. Hydrozirconation of carbon – carbon double and triple bonds with Cp_2ZrHCl (see Section 5.3.1) is chemo- and stereoselective and is a useful route for the functionalization of alkenes and alkynes [118].

A comprehensive literature exists on the extensive subject of hydrido complexes [6, 7, 118–121].

5.3.1. Di(η^5-cyclopentadienyl)chlorohydridozirconium(IV)

Properties (see also Table 6). Dicyclopentadienylzirconium hydride chloride, zirconocene hydride chloride, Schwartz's reagent, Cp_2ZrHCl ($Cp = C_5H_5$), is a white microcrystalline powder, *mp* >300 °C (dec.). Under the influence of light or heat the color changes to pink, then gradually to dark red. The compound

is sensitive to moisture; it is virtually insoluble in the usual organic solvents such as ethers, consistent with its polymeric character. It dissolves in halogenated solvents with evolution of heat, forming Cp_2ZrClX, where X = Cl, Br, or I.

Production. Schwartz's reagent is produced by reaction of zirconocene dichloride (Cp_2ZrCl_2) with $LiAlH_4$ or $LiAlH[OC(CH_3)_3]_3$ in THF solution [122]. The commercial product (Alfa Ventron, Aldrich) is slightly pink.

Uses. Schwartz's reagent is used in limited amounts in organic synthesis for the selective hydrozirconation of alkenes and alkynes. The reaction takes place rapidly and quantitatively at room temperature, forming zirconium alkyls or alkenyls that may be converted into useful functionalized derivatives. For example, reaction with carbon monoxide followed by removal of the zirconium-containing part of the molecule yields a variety of carbonyl compounds [118, 23].

5.3.2. Carbonylhydrido-tris(triphenylphosphine)rhodium(I)

Properties (see also Table 6).
Carbonylhydrido-tris(triphenylphosphine)rhodium(I), carbonyl-tris(triphenylphosphine)rhodium(I) hydride, forms yellow crystals that are stable in air, *mp* 172 – 174 °C in a closed nitrogen-filled capillary. It is readily soluble in benzene, chloroform, and dichloromethane. In solution, one phosphine ligand is readily lost by dissociation to give a 16-electron complex that is an active catalyst for the hydrogenation of alkenes and for hydroformylation [118].

Production. This complex is obtained by the reaction of a solution of $RhCl_3 \cdot 3\,H_2O$ in alcoholic alkali with aqueous formaldehyde (the carbon monoxide source) and an excess of triphenyl phosphine [123]. The commercial product is a microcrystalline powder with a purity of 97 % (Degussa).

Uses. Carbonylhydrido-tris(triphenylphosphine)rhodium(I) is used in industry for the hydroformylation of alkenes by the low pressure oxo (LPO) process developed by Union Carbide, Davy Power Gas, and Johnson Matthey. The reaction takes place rapidly at 25 °C giving a product in which the ratio of *n*- to *iso*-aldehydes is very favorable (ca. 20 : 1), a much higher ratio than can be obtained with cobalt catalysts [119].

6. Handling, Storage, and Transportation

Handling. Most of the alkali and alkaline earth metal hydrides and the complex hydrides of the boron group are unusually reactive and moisture sensitive. They should therefore only be handled by well trained and qualified personnel. On an industrial scale, the use of tight goggles, helmets with face protection, leather gloves, and special protective clothing is essential. Protective impregnated leather or aluminum-covered outer clothing is especially recommended. Sparks caused by static discharge should be prevented by the use of shoes with conducting soles. In the event of skin contact, the affected part should be treated with copious quantities of running water until pH paper gives a neutral reaction. If the eyes are affected, they should immediately be rinsed thoroughly with water; medical attention should be sought. Accidental ingestion should be treated by a physician.

The greatest potential source of danger from hydrides derives from their high hydrogen content. This gas is released in large quantities in a violent exothermic reaction when the easily hydrolyzable hydrides come into contact with water or other protic substances. In a closed vessel, dangerously high pressures can suddenly develop. In open air, gas mixtures are produced that can explode with great violence if ignited. Some hydrides are even more dangerous, being spontaneously flammable when finely divided material comes into contact with moist air, and thus provide a potential source of ignition for any explosive mixture of hydrogen, solvent, and air. Some commercially available hydrides tend to create dust on account of their small particle size and, if they are not sufficiently protected by an inert gas, can cause dangerous dust – air explosions. Fire-fighting equipment including dry powder extinguishers (based on sodium chloride) and breathing apparatus should be kept in readiness.

Smaller, localized fires can be extinguished with powdered calcium carbonate or by dry sand applied to the base of the flames with a shovel. Easily reachable dry powder sprinklers and emergency water basins for washing away alkaline spills are recommended for personal emergency use. Under no circumstances must water, carbon dioxide, or halogenated materials (such as carbon tetrachloride) be used.

Storage. The hydrides described here may be stored indefinitely in the absence of air and moisture, but see Sections 3.8 and 5.3.1.1 for conditions causing the decomposition of lithium aluminum hydride and Cp_2ZrClH, respectively. These chemicals should be stored in a cool, dry, well-ventilated area. Hydrides should not usually be kept in glass containers (with the exception of the transition metal hydrides) owing to the danger of accidental hydrogen pressure build-up leading to bursting of the container.

Transportation. Metal hydrides are classed as dangerous substances to which special transportation regulations apply (RID, ADR, IMDG). The alkali and alkaline earth hydrides and the complex boron and aluminum hydrides are in the Dangerous Goods Class 4.3 (materials that evolve flammable gases in the presence of water) and which includes Subgroups 2 b (solids) and 2 e (solutions). The 12 % alkali-stabilized solution of sodium borohydride is an exception, and is classified in Class 8 (caustic alkali solutions). Lastly, the transition metal hydrides of titanium and zirconium, which are stable to water, fall under Class 4.1 (flammable solids). Every country sets a limit to the amount of hydride per container, frequently 10 kg, that may be carried. Further details should be obtained from the producers. These hydrides may not be sent by mail.

7. Toxicology and Occupational Health

The alkali and alkaline earth metal hydrides, and the complex hydrides of group 13 are extremely reactive substances, which on contact with water or moist air give off hydrogen and are converted to the corresponding hydroxide. Considerable quantities of heat are often released, and in conjunction with the caustic effect of the alkaline hydroxides this leads to severe irritation of the skin and mucous membranes. Dust produced will attack the eyes and the respiratory tract. If ingested, these materials cause severe damage to the mouth and throat. If they were to reach the stomach the acid there would react rapidly even with those hydrides that are relatively resistant to hydrolysis, e.g., $NaBH_4$ and KBH_4, releasing large volumes of hydrogen, which can cause embolism.

Compared with the harmful effects resulting from the alkaline nature of these materials, the toxic properties of the associated metals (e.g., B, Li, Al) are of relatively small concern. An exception is beryllium hydride, since beryllium compounds are extremely poisonous and can also cause dermatitis and cancer [124]. Further information regarding these elements may be found in reference works [124–128] and the material safety data sheets issued by the hydride producers.

Special safety precautions must be observed when working with *sodium cyanoborohydride* as extremely toxic hydrogen cyanide (MAK 10 ppm) can be generated, especially in acidic solutions. Toxicological investigations have shown that aqueous $NaBH_3CN$ solutions do not cause skin or eye irritation, whereas solutions in THF are easily absorbed through the skin and have severe toxic effects. The oral LD_{50} lies between 10 and 100 mg/kg [129].

1. Saturated Hydrocarbons

The class of saturated hydrocarbons comprises a myriad of individual compounds. A large number of the theoretically possible saturated hydrocarbons is known [1], although only a limited number of individual saturated hydrocarbons are used as raw materials in the chemical industry.

1.1. Physical Properties

Saturated hydrocarbons are colorless nonpolar substances, immiscible with polar solvents, but miscible with many nonpolar organic solvents. Some physical properties are given in Table 1. The boiling points and, starting with C_3, melting points of *n*-alkanes increase with increasing molecular mass. At 20 °C and atmospheric pressure, C_1 to C_4 *n*-alkanes are gases, C_5 to C_{16} are liquid, and from C_{17} solid. *i*-Alkanes do not display a definite correlation between the number of carbon atoms and their boiling- and melting points. The boiling points of *i*-alkanes all are lower than those of the corresponding *n*-alkanes; this is also true for many of the melting points. Furthermore, the boiling points of isomeric alkanes decrease with increasing degree of branching. The boiling points and melting points of cycloalkanes are generally higher than those of *n*-alkanes having the same number of carbon atoms (Table 1).

The density of the saturated hydrocarbons in the liquid state at 20 °C is <1 g/cm^3; it varies from 0.6 g/cm^3 for compounds with low carbon numbers to 0.8 g/cm^3 for compounds with high carbon numbers (Table 1). Additional physical properties are compiled in Tables 2, 3, 4, 5.

1.2. Chemical Properties

Alkanes and cycloalkanes are saturated, nonpolar, and lack functional groups; such hydrocarbons can undergo reaction only after cleavage of C−H or C−C bonds. Consequently, the scope of primary reaction steps is essentially limited to dehydrogenation, substitution, and chain- or ring cleavage. Saturated hydrocarbons cannot undergo addition reactions, which represent a versatile synthetic tool for unsaturated hydrocarbons (see Chap. 2). Most industrial reactions involving saturated hydrocarbons are radical reactions, e.g., thermal cracking, oxidation, sulfoxidation, halogenation, sulfochlorination, and nitration. Industrial ionic reactions of saturated hydrocarbons are restricted to acid-catalyzed processes with strong acids. Such reactions are employed mainly in the processing of petroleum by catalytic cracking, isomerization, and alkylation; they yield complex mixtures of products. Other ionic reactions of saturated hydrocarbons can be carried out with super acids (e.g., FSO_3H-SbF_5, $HF-SbF_5$): the alkylation of alkanes by alkanes [3], alkylation of benzene by alkanes [3], and ionic chlorination [5] and bromination [6] of alkanes have been explored, but are not used industrially (see also →Acylation and Alkylation.

Reactions of saturated hydrocarbons, because of the lack of functional groups, are nonselective, with respect to both the region of attack (regioselectivity) and the number of reaction sites (degree of substitution), unless the molecule possesses specific structural features, e.g., tertiary hydrogen atoms. Such reactions frequently afford mixtures of isomeric or structurally analogous compounds which can only be separated with difficulty or not at all.

On the basis of free enthalpy of formation (see Table 2) most of the saturated hydrocarbons are thermodynamically unstable with respect to the elements carbon and hydrogen. They are, however, kinetically stable at ambient temperature. Thermal decomposition of saturated hydrocarbons proceeds stepwise by loss of hydrogen or hydrocarbon fragments with concomitant formation of industrially useful unsaturated cracking products, such as acetylene, olefins, or aromatic hydrocarbons.

[a] For saturation pressure (triple point).
[b] At saturation pressure.
[c] For the super-cooled liquid below the normal melting point.
[d] Value for the melting point of the metastable crystalline form.

On ignition, mixtures of saturated hydrocarbons and oxygen or air may lead to combustion or explosion, depending on the ratio of hydrocarbon and oxygen. Such reactions can be initiated either by imposed ignition or, if the ignition temperature of the mixture is exceeded, by self-ignition. These reactions are the basis for the use of hydrocarbons as heating- and engine fuel. Pertinent fuel properties of individual saturated hydrocarbons are summarized in Table 4.

Table 2. Molar enthalpies of fusion, vaporization and combustion [2]

1.3. Production

By far the largest amount of saturated hydrocarbons is obtained from the natural sources *natural gas* and *petroleum*, either by isolation or by suitable conversion reactions. Additional sources include various products derived from coal processing. A number of saturated hydrocarbons, unavailable from natural sources, are produced by special synthesis or by conversion processes.

1.3.1. From Natural Gas and Petroleum

Natural Gas contains methane as the single major component (see also →Methane;

Table 4. Critical data and molar heat capacities of saturated hydrocarbons [2]

Figure 1. Saturated hydrocarbons from natural gas and from petroleum

→Natural Gas). Depending on the particular source, natural gas may also contain acyclic saturated hydrocarbons up to C_5 in proportions that permit their isolation [10]. The isolation of individual compounds from natural gas (see Figure 1) can be performed either by absorption or by partial condensation at low temperature, followed by distillation.

Petroleum is the most abundant source of saturated hydrocarbons, both with respect to the absolute amount and to the variety of individual compounds. Petroleum is separated into individual fractions by distillation in a refinery (see also →Oil Refining). Such fractions contain several (liquefied petroleum gas, LPG; →Liquefied Petroleum Gas) or many individual hydrocarbons (all other fractions); these fractions can be used as such or processed further for use as heating- or engine fuels, as lubricants, as raw materials for the production of petrochemicals (synthesis gas →Gas Production, acetylene, olefins, aromatics), or for the recovery of industrially important alkanes and cycloalkanes.

From the liquefied petroleum gas fraction, propane, *n*-butane, and *i*-butane are isolated by distillation. *n*-Pentane and *i*-pentane can be isolated from the liquid components of natural gas or from light gasoline (naphtha) either by molecular sieve separation or by superfractionation [11]. Steam-cracking of light gasoline provides, among other products, cyclopentadiene (→Cyclopentadiene and Cyclopentene), benzene (→Benzene), and 1,3-butadiene (→Butadiene); these can, in turn, be converted into the C_5-, C_6-, C_8-, and C_{12}-cycloalkanes. Catalytic reforming of heavy gasoline provides C_6- to C_8-aromatics, which can subsequently be converted into cyclohexane (→Cyclohexane), e.g., the C_7- and C_8-aromatics are hydrodealkylated, and the ensuing benzene subsequently hydrogenated. From the higher boiling petroleum, gas-oil, and wax distillate fractions, mixtures

of homologous *n*-alkanes are isolated by techniques, such as molecular sieve separation or urea extractive crystallization. Paraffin waxes can also be isolated by precipitation with suitable solvents.

Higher boiling petroleum distillates and distillation residues can be converted into mixtures of lower molecular mass hydrocarbons by hydrocracking [12, 13]. From such mixtures, saturated C_3–C_5-hydrocarbons and a broad spectrum of higher *n*-alkanes can be recovered.

Although petroleum and the various petroleum distillates contain a large variety of other saturated hydrocarbons in addition to those already mentioned, the recovery and subsequent industrial use of individual compounds is largely confined to those depicted in Figure 1; the increasing number of structural isomers with increasing molecular mass poses severe limitations on the economical separation of individual compounds from such distillate mixtures on an industrial scale.

1.3.2. From Coal and Coal-Derived Products

For a long time the most important sources of saturated hydrocarbons were coal and the products derived from the liquefaction, coking, and gasification of coal (→Coal; Coal Liquefaction; →Coal Pyrolysis). These sources became less important when natural gas and petroleum became essential raw materials for organic chemicals [14, 15].

The *liquefaction of coal* provided the greatest variety of saturated hydrocarbons. The Fischer–Tropsch Synthesis can produce alkanes in the range C_1 to C_{30} or higher, depending on the process variant (→Coal Liquefaction, Chap. 2.2.) [16–18]: the fluidized bed synthesis affords predominantly liquid hydrocarbons in the gasoline range, along with gases from C_1 to C_4. The liquid hydrocarbons contain considerable proportions of branched and olefinic compounds. The fixed bed synthesis provides higher molecular mass hydrocarbons in the range of diesel oil or paraffin wax. These products are rich in *n*-alkanes and are, therefore, suitable raw materials for detergents and for wax products. Suitable fractions may also serve as raw materials for cracking and reforming processes.

The various processes for the *hydrogenation of coal* [19–21] or of coal tar afford predominantly liquid products in the boiling range of gasoline, which are rich in aromatics, and minor amounts of C_1- to C_4-alkanes. From the gasoline fractions, benzene can be recovered and hydrogenated to cyclohexane. After the recovery of benzene, the remaining mixtures can be used as feed materials for steam crackers for the production of olefins.

Coking of coal produces methane. In addition, high temperature processes produce benzene, which can be hydrogenated to cyclohexane [22, 23]. Low temperature coking of soft coal provides a tar, from which paraffin wax may be recovered.

Gasification of coal [24] affords mainly carbon monoxide and hydrogen, which can be converted into methane by nickel-catalyzed reactions or into a range of alkanes by the Fischer–Tropsch process. Up to 10 % of methane and higher hydrocarbons such as naphtha and benzene are formed in addition to carbon monoxide and hydrogen if the gasification is carried out at elevated pressure [25].

1.3.3. By Synthesis and by Conversion of other Hydrocarbons

The major processing techniques are *cyclization, hydrogenation,* and *isomerization,* forming the basis of the industrial production of most cycloalkanes. Other techniques include *alkylation* of alkenes with alkanes to provide *i*-alkanes, and hydrocracking to give predominantly low molecular mass *i*- and *n*-alkanes, including methane.

Cyclization and Hydrogenation. Among the cycloalkanes only those containing a 5- or a 6-membered ring are directly available from natural sources, i.e., from petroleum or coal-derived products. Steamcracking of naphtha or gas oil produces cyclopentadiene as a byproduct, which can be converted into cyclopentane by catalytic hydrogenation. Similarly, cyclohexane is produced by catalytic hydrogenation of benzene, which in turn is formed by steam cracking of liquid hydrocarbons, by catalytic reforming of heavy gasoline, or by coking of coal.

The skeletons of all other industrially produced cycloalkanes are synthesized from acyclic precursors. Although there is a wide variety of synthetic procedures for such reactions, only a limited number are used industrially. Of prime importance are cycloaddition reactions of acyclic unsaturated compounds followed by hydrogenation of the resulting unsaturated cyclic products: Thus, [4 + 2]-cycloaddition (Diels – Alder reaction) of conjugated dienes and monoolefins yields saturated 6-membered ring compounds via cyclohexene intermediates, e.g., the synthesis of cyclohexane from 1,3-butadiene and ethylene [26]:

the catalyzed [4 + 4] -cycloaddition of 1,3-butadiene to give cyclooctane via 1,5-cyclooctadiene;

and the catalyzed [4 + 4 + 4] -cyclotrimerization of 1,3-butadiene to form cyclododecane via 1,5,9-cyclododecatriene:

Cyclizations that lead to small (C_3-, C_4-) rings are not industrially important, although various laboratory methods are available [27]. Examples include the coupling of terminal carbon atoms by elimination of suitable α,ω-substituents from acyclic compounds, e.g., α,ω-dihalides, ω-halogenated ketones, esters, or nitriles (Eq. 1), addition of carbenes, to olefins to give cyclopropanes (Eq. 2) and [2 + 2] -cycloadditions of suitable unsaturated compounds, such as olefins, allenes, or acetylenes, to give cyclobutanes (Eq. 3) [28] (see figure at top of next column).

Most of these synthetic methods yield substituted or unsaturated cyclic compounds in the cyclization step. These primary products can be subsequently converted into the corresponding cycloalkanes by suitable measures.

(1)

(2)

(3)

Isomerization and Alkylation. On account of their specific properties (antiknock activity, possibility for selective reactions), some *i*-alkanes are in higher demand than can be met by natural sources. *i*-Alkanes are produced either by acid-catalyzed isomerization of *n*-alkanes or by acid-catalyzed alkylation of olefins with *i*-alkanes. The most important isomerizations are the conversion of *n*-butane to *i*-butane, *n*-pentane to *i*-pentane, and *n*-hexane to *i*-hexane [29, 30]. Industrially important alkylations include the reaction of *i*-butane with propylene or with butenes to give highly branched C_7- or C_8-alkanes, respectively (see also →Oil Refining). The latter exhibit high octane numbers [30, 31].

Hydrocracking. A range of acyclic saturated hydrocarbons having low carbon numbers is accessible by catalyzed hydrocracking of heavy distillates or distillation residues. Hydrocracking of distillates can be optimized by adjusting the reaction conditions, so that the products are predominantly in the range of liquefied petroleum gases, including *i*-butane [13], or in the range of middle distillates [32]. The cracking of petroleum distillates with steam over a nickel catalyst produces methane [33, 34].

1.4. Uses

The major use of saturated hydrocarbons is as a mixture, sometimes with unsaturated or aromatic compounds, as heating fuels, motor fuels and lubricants. Saturated hydrocarbons also serve as raw materials for the production of carbon black. In the chemical industry, the following processes are important (Fig. 2, see next page).

Thermal Cracking. Thermal cracking of individual or mixed saturated hydrocarbons is

Figure 2. Industrial use of saturated hydrocarbons

the basis for the petrochemical production of acetylene, olefins, diolefins, and to some extent BTX aromatics: high temperature pyrolysis at >1000 °C affords acetylene (→Acetylene) and, depending on the hydrocarbon feed and the particular process applied, ethylene. The range of hydrocarbon feed materials can vary from methane to crude oil. Medium temperature pyrolysis at 750 – 900 °C in the presence of inert diluents such as steam (steam-cracking) or hydrogen (hydropyrolysis) yields ethylene (→ Ethylene). A wide range of hydrocarbons, e.g., ethane, liquefied petroleum gas, naphtha, and gas oil may serve as raw material, and increasing proportions of C_3- to C_5-olefins, C_4- and C_5-dienes, and C_6- to C_8-aromatics are coproduced with increasing molecular mass of the feed material. Pyrolysis of petroleum waxes at 500 – 600 °C affords mixtures of homologous olefins with predominantly terminal double bonds.

Catalytic Dehydrogenation. Catalytic dehydrogenation of acyclic saturated hydrocarbon atoms yields mono- and/or diolefins with the same number of carbon atoms. Industrial processes include the production of butenes and butadiene from *n*-butane, of isoprene from *i*-pentane, and C_6- to C_{19}-monoolefins, mainly with internal double bonds, from the corresponding *n*-alkanes [35]. More recently, improved processes for the production of ethylene, propene, and *i*-butene by catalytic dehydrogenation of the corresponding saturated hydrocarbons have been developed [36]. Catalytic dehydrogenation of cyclohexane and methyl cyclohexanes yields benzene and methylbenzenes, respectively.

Catalytic dehydrocyclooligomerization of propane and *n*-butane over modified zeolite catalysts represents a new method for the production of BTX-aromatics [37]. The process is apparently ready for industrial application.

Partial Oxidation. Partial oxidation of saturated hydrocarbons either by catalyzed reaction with steam (steam reforming) or by noncatalyzed reaction with deficient amounts of oxygen affords a mixture of carbon monoxide and hydrogen, which is used as town gas or as synthesis gas (→Gas Production). Desulfurized saturated hydrocarbons from methane to compounds with *bp* ca. 200 °C are suitable feed materials for catalytic processes; for noncatalytic processes all hydrocarbons may be used from methane to distillation residues.

Selective Oxidation. Selective oxidation represents the most important tool for the introduction of oxygen-containing functional groups into saturated hydrocarbons: Liquid-phase autoxidation of *i*-butane with air yields *tert*-butylhydroperoxide; the latter is used for the selective oxidation of propene to propylene oxide [38]. Liquid-phase oxidation of *n*-alkanes or cycloalkanes in the presence of boric acid affords the corresponding secondary alcohols. The reaction is used industrially for the oxidation of C_{10}- to C_{20}-*n*-alkanes, providing raw materials for detergents and for the oxidation of cyclododecane to cyclododecanol as an intermediate for the production of nylon 12. Catalyzed liquid-phase oxidation of *n*-alkanes and cycloalkanes in the absence of boric acid leads to mixtures of secondary alcohols and ketones or to carboxylic acids, depending on the reaction conditions: oxidation of cyclohexane leads to a mixture of cyclohexanol and cyclohexanone (→Cyclohexanol and Cyclohexanone, Chap. 3.2.); oxidation of *n*-butane gives acetic acid (→Acetic Acid, Chap. 4.2.); oxidation of longer chain *n*-alkanes produces mixtures of fatty acids; and oxidation of cyclohexane gives adipic acid. (→Adipic Acid, Chap. 4.). Liquid phase oxidation of bicyclo [4.4.0] decane yields the corresponding tertiary hydroperoxide, which is eventually converted into sebacic acid by a sequence of reaction steps [39].

Heterogeneously catalyzed gas-phase oxidation of *n*-butane has been used industrially as an attractive alternative for the production of maleic anhydride [40]. Selective oxidation of methane to methanol [41] or formaldehyde [42] and of *i*-butane to methacrylic acid [43] has been examined, but is not yet used industrially.

Oxidative Couplings. Oxidative coupling of methane either with itself to give ethane and ethylene [44] (Eq. 4), or with compounds having activated methyl groups (Eq. 5) to give terminal olefinic compounds [45] has been investigated, but is not yet industrially used.

$$CH_4 \xrightarrow[-H_2O]{O_2} CH_3CH_3 + CH_2=CH_2 \quad (4)$$

$$CH_4 + CH_3-X \xrightarrow[-H_2O]{O_2} CH_2=CH-X \quad (5)$$

$$X = -CH=CH_2,\ -C(CH_3)=CH_2,\ -C_6H_5,\ -C\equiv N$$

Three-Component Oxidation. Three-component oxidation allows introduction of hetero atoms or groups of hetero atoms other than oxygen into saturated hydrocarbons. The radical-induced action of both oxygen and sulfur dioxide (sulfoxidation) on alkanes yields the corresponding alkanesulfonic acids. The latter, produced from C_{14}– to C_{18}–*n*-alkanes, are useful as raw materials for detergents. The heterogeneously catalyzed reaction of oxygen and ammonia with methane (ammoxidation) affords hydrogen cyanide. The latter reaction can be also carried out in the absence of oxygen as a two-component codehydrogenation. The reaction of oxygen and ammonia with propane to give acrylonitrile has recently been explored.

Chlorinations. Chlorination of saturated hydrocarbons yields mono- or polychlorinated hydrocarbons, depending on conditions. The following reactions are used industrially: Chlorination of methane to give the four chloromethanes (→Chlorinated Hydrocarbons, Chap. 1.3.1.); the chlorination of *n*-alkanes to give mono- or polychlorinated alkanes having the same number of carbon atoms and chlorinolysis of low molecular mass alkanes or chloroalkanes to give tetrachloroethene and tetrachloromethane. Reaction of chlorine and sulfur dioxide together with alkanes yields alkanesulfonyl chlorides,

which in turn can be converted into the corresponding sulfonic acids, sulfonates, sulfonamides, or sulfonic esters.

Photonitrosation. Photonitrosation of saturated alkanes with nitrosyl chloride yields oximes via labile secondary nitroso compounds. The method has been used for the production of caprolactam from cyclohexane (→Caprolactam, Chap. 4.2.).

Nitrosation. Nitrosation of saturated hydrocarbons with nitric acid has been carried out with low molecular mass alkanes, particularly with propane in the gas phase. The reaction gave mixtures of nitro compounds with the same number of and fewer carbon atoms than those of the starting alkanes. Such mixtures are useful as specialty solvents, e.g., for polymers.

Reaction with Sulfur. Reaction of methane with sulfur gives carbon disulfide in high yields with hydrogen sulfide as byproduct. The reaction can be performed by thermal or catalytic methods (→Carbon Disulfide, Chap. 4.).

Fermentation. Fermentation of certain saturated hydrocarbons by microorganisms (yeast, bacteria) yields single cell proteins [46–50]. The microorganisms oxidize the hydrocarbons in the presence of oxygen and nutrients with concomitant formation of protein-containing cells. Certain microorganisms are specific for the fermentation of *n*-alkanes. Industrial processes have therefore been developed both for the fermentation of isolated *n*-alkanes and for *n*-alkanes in admixture with branched or cyclic hydrocarbons (e.g., diesel oil). The products obtained are used as animal feed.

1.5. Individual Saturated Hydrocarbons

Methane, Cyclohexane, and *Waxes* are separate keywords. Of the other saturated hydrocarbons only those used industrially will be discussed.

Ethane. Ethane is present in many natural gas sources and in refinery gases; it can be recovered for industrial use. Furthermore, ethane is formed in thermal- and hydrocracking of hydrocarbons (→ Oil Refining) and in the liquefaction of coal (→ Coal Liquefaction). The single most important industrial use for ethane is the production of ethylene by steam-cracking (→ Ethylene, Chap. 5.1.3.). Thermally-induced chlorination of ethane yields predominantly monochloro-, 1,1-dichloro-, or 1,1,1-trichloroethane, depending on the conditions used. Combined chlorination and oxichlorination of ethane in a salt melt affords vinyl chloride [51]. Reaction of ethane with nitric acid in the gas phase yields nitroethane and nitromethane (→ Nitro Compounds, Aliphatic).

Propane. Propane is a component of liquefied petroleum gas (LPG), which is derived from natural gas or petroleum. Propane can be recovered from LPG by distillation. The major industrial use of propane is the production of ethylene and propene by the steam cracking process (→ Ethylene, Chap. 5.1.3.). Chlorinolysis of propane at elevated temperature yields a mixture of tetrachloroethene and tetrachloromethane. The conversion of propane into BTX aromatics by zeolite-catalyzed dehydrocyclooligomerization has been developed recently and may find industrial application. Liquefied propane is used for the deasphalting of petroleum residues.

***n*-Butane.** *n*-Butane can be recovered from LPG by distillation; it has a variety of industrial uses: steamcracking yields ethylene and propene, catalytic dehydrogenation yields butadiene (→Butadiene), and acid-catalyzed isomerization provides *i*-butane. Oxidation of *n*-butane in the gas phase with heterogeneous catalysis is a modern process for the production of maleic anhydride [40]. Noncatalyzed oxidation of *n*-butane in the liquid or gas phase has been used industrially to produce acetic acid [52] (→Acetic Acid, Chap. 4.2.).

***i*-Butane.** *i*-Butane can be obtained either by recovery from LPG or by isomerization of *n*-butane. Traditional industrial uses include the production of high octane engine fuel by the alkylation of olefins [30,31] and liquid-phase autoxidation of *i*-butane to give *tert*-butylhydroperoxide. Recent developments comprise improved processes for the catalytic dehydrogenation of *i*-butane [53] to satisfy the in-

creasing demand for *i*-butene as a pecursor for methyl *tert*-butyl ether (MTBE) (→Methyl Tert-Butyl Ether), and the production of methacrylic acid from *i*-butane by oxidation [43].

***n*-Pentane and *i*-Pentane.** Both isomers are present in light gasoline fractions and can be recovered individually by superfractionation [11,54], possibly in combination with molecular sieve separation. *n*-Pentane is used as a solvent and for the production of *i*-pentane by acid-catalyzed isomerization [26]. *i*-Pentane is used as a blending component for high octane gasoline and for the production of isoprene by catalytic dehydrogenation [53,54].

***n*-Hexane.** *n*-Hexane can be isolated from suitable sources (e.g., light gasoline or BTX raffinates) by superfractionation, or by molecular sieve separation. It is used for the extraction of vegetable oils (e.g., from soybeans), as a solvent in chemical reactions (e.g., for coordination complex catalyzed polymerization of olefins) and in adhesive formulations.

Higher *n*-Alkanes. *n*-Alkanes having more than six carbon atoms are not isolated individually but as mixtures of several homologues. Suitable sources are the appropriate petroleum distillate fractions, from which the *n*-paraffins can be isolated in high isomeric purity (≥95 % linearity) by selective separation (e.g., molecular sieve separation or urea extractive crystallization). They are used mainly in applications for which *i*-alkanes are not acceptable for biological reasons, e.g., the production of detergents or proteins. Catalyzed gas-phase dehydrogenation of *n*-alkanes over noble metal catalysts and at low conversion (ca. 10 %) yields the corresponding *n*-alkenes with predominantly internal double bonds. The alkenes can be isolated in high purity by selective molecular sieve processes [35, 56]. *n*-Alkenes in the range C_7 to C_{10} are used as raw materials for the production of flexibilizers, by oxo-synthesis with hydrogen and carbon monoxide. *n*-Alkenes in the range C_{10} to C_{19} are used for the production of biodegradable detergents: acid-catalyzed reaction of C_{10}- to C_{13}-*n*-alkenes with benzene, followed by sulfonation and neutralization of the ensuing alkylbenzene sulfonic acids, affords linear alkylbenzenesulfonate (LABS) detergents. Oxo-reaction of C_{10}- to C_{19}-*n*-alkenes yields C_{11}- to C_{20}-alcohols, which are converted into nonionic detergents by reaction with ethylene oxide, or into anionic detergents by reaction with sulfur trioxide or chlorosulfonic acid. Liquid-phase oxidation of *n*-alkanes with oxygen in the presence of boric acid yields predominantly secondary alcohols. The latter can be dehydrated to the corresponding *n*-alkenes. The C_{12}- to C_{19}-alcohols are also used for the production of both ionic and nonionic detergents.

Chlorination of *n*-alkanes yields mono- or polychlorinated alkanes, depending on the conditions. Mixtures of C_{10}- to C_{13}-monochloroalkanes are used for the production of linear alkylbenzenes as raw materials for LABS-detergents. For this, the chloroalkanes are either directly reacted with benzene or they are dehydrochlorinated to the corresponding *n*-alkenes, which are then used to alkylate benzene. Polychlorinated *n*-alkanes are used in a number of special applications. *n*-Alkanes in the range of C_{10} to C_{21} are suitable substrates for the production of single cell proteins by fermentation. The microorganisms used selectively attack *n*-alkanes, so that industrial processes have been developed in which either isolated *n*-alkanes or the appropriate petroleum distillates containing *n*-alkanes (petroleum-, gas oil-, or lube oil fractions) are used as starting materials.

Solid *n*-alkanes (paraffin waxes) are used in a variety of applications, both as such and as feed materials in cracking, oxidation and chlorination.

Cycloalkanes. Of the various accessible cycloalkanes, only cyclohexane and cyclododecane are used industrially on a large scale; cyclooctane is used on a relatively small scale. The strained C_3- and C_4-cycloalkanes are not produced industrially. *Cyclopentane* is present in natural hydrocarbon sources and is formed as a byproduct in the processing of cracking products, e.g., by hydrogenation of cyclopentadiene or cyclopentene in the C_5-fraction of steamcracked products. No important industrial use exists for cyclopentane.

Cyclooctane

is accessible by catalytic hydrogenation of 1,5-cyclooctadiene. Liquid-phase oxidation of the former with air yields 1,8-octanedicarbox-

ylic acid, which is used on a moderate scale for the production of nylon 68.

Cyclododecane

is produced by liquid-phase hydrogenation of 1,5,9-cyclododecatriene over nickel catalysts. Liquid-phase oxidation of cyclododecane with air in the presence of boric acid yields mixtures of cyclododecanol and cyclododecanone in high selectivity. Further oxidation of such alcohol – ketone mixtures with nitric acid gives 1,12-dodecanedicarboxylic acid, used for the production of polyamides, polyesters, and synthetic lubricating oils. Catalyzed dehydrogenation of alcohol-ketone mixtures in the liquid phase yields cyclododecanone, which is then converted into laurinlactam and nylon 12.

Bicyclo [4.4.0] decane (decalin) is obtained by catalytic hydrogenation of naphthalene. Liquid-phase oxidation of decalin with oxygen gives the corresponding tertiary hydroperoxide, which is eventually converted into 1,10-decanedicarboxylic acid (sebacic acid) by a four-step sequence [39].

2. Olefins

Olefins are aliphatic hydrocarbons containing at least one carbon–carbon double bond. Monoolefins (alkenes) contain a single C=C double bond and form a homologous series with the empirical formula C_nH_{2n}. Hydrocarbons with two double bonds are differentiated according to the relative positions of the double bonds: in cumulated dienes (cumulenes, allenes) they are immediately adjacent to each other; in conjugated dienes they are separated by a single bond; and in other diolefins, the double bonds are isolated from each other.

More highly unsaturated polyenes are known, e.g., trienes, tetraenes. The name olefin is derived from the property of these compounds to form oily liquids on reaction with halogens (*gaz oléfiant,* oil-forming gas).

The industrial importance of olefins started in the 1950s when the lower olefins became widely available from thermal cracking of wet natural gas and petroleum fractions, displacing acetylene (ethyne) as the dominant commodity chemical (→Acetylene). In the time since then, ethene (ethylene), propene, 1,3-butadiene, and isoprene (2-methyl-1,3-butadiene) have found wide application, especially for synthetic polymers (→Butadiene ; →Ethylene ; →Isoprene ; →Polyolefins ; →Propene).

2.1. Monoolefins

The low molecular mass monoolefins ethylene, propene, styrene, cyclopentene, and the butenes are separate keywords: (→Butenes; →Cyclopentadiene and Cyclopentene; →Ethylene). Among the higher olefins ($C_6 - C_{18}$), the linear α-olefins are of particular industrial interest.

2.1.1. Properties

Physical Properties. Under normal conditions, the olefins from ethylene to the butenes are gases; from the pentenes to 1-octadecene liquids; and from 1-icosene onwards solids. These thermal phase transitions do not differ significantly from those of the corresponding saturated hydrocarbons (Chap. 1). The density of olefins ranges from 0.63 to 0.79 g/cm^3, only a few percent higher than those of the corresponding alkanes.

The heats of combustion of alkenes and the corresponding alkanes are also nearly identical. Olefins have low solubility in water or are insoluble; they dissolve well in most organic solvents, e.g., alcohols, ethers, and aromatic hydrocarbons. Some physical properties of important monoolefins are listed in Table 6 (see next page).

Chemical Properties. The chemistry of monoolefins is dominated by the reactive double bond. Some important reactions of olefins are summarized in Table 7 (see page after next).

Table 6. Physical properties of monoolefins

Olefin	CAS registry number	*mp*, °C	*bp*, [a] °C	d^{20}	n^{20}

Most *addition reactions* proceed by an electrophilic mechanism via carbonium ions. Chlorination and bromination yields the trans adducts. Hydrohalogenation generally follows Markovnikov's rule to give a product containing halogen linked to secondary carbon. Addition of sulfuric acid to olefins affords alkyl sulfates, which are readily hydrolyzed to alcohols; the reaction corresponds to the acid-catalyzed addition of water. Ethanol, isopropylalcohol,

and *tert*-butyl alcohol are produced industrially by this method from ethylene, propene, and isobutene, respectively (→Alcohols, Aliphatic, Chap. 2.3.7.).

Sulfonation	SO_3, NaOH	alkenesulfonates
Hydroboration	B_2H_6	trialkylboranes
Alkylation	a) of aromatics, with a Friedel – Crafts catalyst	alkylaromatics
	b) of isoalkanes, catalyst: H^+	branched alkanes
Polymerization	Catalyst: radicals, metal complexes	polymers
Oligomerization	Catalyst: metal complexes, BF_3	oligomers

Hydrogenation of olefins to alkanes requires a catalyst: Raney nickel is most frequently used industrially, although platinum-group metals are also used (→Hydrogenation and Dehydrogenation).

Epoxidation of ethylene may be carried out with oxygen in the presence of a silver catalyst. Higher olefins are converted to epoxides using hydroperoxides or peracids (→Epoxides). A related reaction is the hydroxylation of olefins with hydrogen peroxide in glacial acetic acid: an epoxide is initially formed, which subsequently reacts with water in the acidic medium to form a glycol.

Another olefin oxidation is the *Wacker oxidation* of ethylene to acetaldehyde (→Acetaldehyde, Chap. 4.3.1.). The stoichiometric reaction of ethylene with water and palladium(II) chloride yields acetaldehyde and palladium metal. Addition of copper(II) chloride converts the stoichiometric reaction into a catalytic process, wherein the copper(II) chloride reoxidizes the palladium to palladium(II) chloride the resulting copper(I) chloride is reoxidized to copper(II) chloride by atmospheric oxygen in hydrochloric acid solution.

Ozonolysis is used mainly for structure determination of olefins, but may also be used preparatively. Reaction of olefins with carbon monoxide and additional reagents (e.g., hydrogen, water, alcohols) leads to a plethora of valuable products (e.g., aldehydes, alcohols, carboxylic acids, esters). These reactions proceed under catalysis by transition metals, e.g., hydroformylations (Oxo process) with rhodium- or cobalt carbonyls.

Sulfonation of olefins leads to alkenesulfonic acids, which are used as detergents (→ Laundry Detergents). Hydroboration is used to generate primary alcohols via trialkylboranes. In contrast to the direct addition of water, this pathway is regioselective to yield the anti-Markovnikov products.

Olefins may undergo a number of reactions resulting in new C-C bonds. With aromatic compounds alkylaromatics are formed by the Friedel – Crafts reaction; with isoalkanes chain-lengthened, branched hydrocarbons, which are used in motor fuels, are formed (→Automotive Fuels). Olefins may also react with themselves or each other to form oligomers and polymers.

The industrial use of the higher monoolefins is discussed in Section 2.1.3.

2.1.2. Production of Higher Olefins

Olefins are synthesized on a laboratory scale by a variety of routes: e.g., selective hydrogenation of alkynes; dehydration of alcohols; pyrolysis of alkyl lithium compounds; the Wittig reaction; the Peterson reaction; and deoxygenation of vicinal diols. Only processes starting with cheap raw materials have gained industrial importance for the production of higher olefins. The following discussion considers processes that start either with long-chain alkanes (Section 2.1.2.1) or those that build up longer chain olefins from their lower molecular mass homologues (Section 2.1.2.2).

Table 8. Composition of fractions (wt %) obtained in a paraffin cracking process (Chevron process)

Paraffins	2	2	2	2	2	9
Aromatics	0.4	0.2	0	0	0	0

2.1.2.1. Production from Paraffins

Thermal Cracking of Waxes. Thermal cracking of long chain alkanes yields mainly α-olefins.

$$R^1-CH_2CH_2CH_2CH_2-R^2 \longrightarrow R^1-CH{=}CH_2 + R^2-CH{=}CH_2 + H_2$$

Thermal cracking involves a radical mechanism. Cleavage of a C-C bond leads to carbon radicals, which are converted into olefins by loss of a hydrogen atom. The latter predominantly combine to form hydrogen; a small fraction reacts with carbon radicals to form alkanes.

To generate linear α-olefins, linear alkanes (waxes) must be used. Suitable sources are the petroleum, diesel oil, and lubricant fractions of paraffin-based crude oils. One possibility of enriching the linear paraffin content of such fractions is to dilute with a suitable solvent, followed by chilling to crystallize a mixture of paraffins. Linear paraffins can be separated from their branched and cyclic analogs by subsequent treatment with molecular sieves. Another method for the separation of *n*-paraffins, especially suitable for long-chain ($>C_{20}$) species, is *extractive crystallization with urea*. This process uses the property of urea to form inclusion compounds with linear paraffins, but not with branched or cyclic alkanes, or aromatics. During crystallization the urea molecules assemble to form cavities having a diameter of 0.53 nm, in which only linear alkanes can be accommodated. The alkanes are then liberated by subsequent decomposition of the complex, e.g., with water at 75 °C. Industrial processes use solid urea (Nurex process) or its saturated aqueous solution (Edeleanu process).

The long-chain paraffins are then cracked by first heating the vapor to 400 °C within a few seconds, followed by thermolysis at 500 – 600 °C in the presence of steam. Rapid quenching of the reaction mixture reduces side reactions such as isomerization or cyclization.

Using $C_{18}-C_{36}$ alkanes as starting material, α-olefins with even and odd numbers of carbon atoms in the range C_6-C_{20} are obtained; only small amounts of paraffins are present. Byproducts include nonterminal olefins, conjugated and nonconjugated dienes, and traces of aromatics. Typical composition of the olefin fractions from paraffin cracking are given in Table 8.

The dependence of product quality on the starting material and process parameters is discussed in a review [66]; catalytic cracking and cracking in the presence of oxygen are also reviewed. The latter processes have not gained acceptance because of the presence of numerous byproducts, e.g., branched olefins and oxidation products.

The first industrial paraffin cracking plant was brought into service in 1941 by Shell at Stanlow (United Kingdom). Other plants were built at Pernis (The Netherlands) and Berre (France). A U.S. paraffin cracking plant owned by Chevron is located in Richmond, California. Future expansion of paraffin cracking processes is unlikely because of the limited flexibility of paraffin cracking plants with respect to carbon number distribution, the limited supply of paraffin-containing crudes, the high percentage ($\geq$10 %) of byproducts in the α-olefin cut, and because of more efficient competitive processes.

Catalytic Dehydrogenation. Catalytic dehydrogenation of paraffins leads to olefins with the same number of carbon atoms and with random location of the double bond along the chain. Thermally, this reaction cannot be carried out economically because the energy required to cleave a C-H bond (365 kJ/mol) significantly exceeds that for breaking a C-C bond (245 kJ/mol). Cracking of longer chain hydrocarbons is, therefore, favored over dehydrogenation; however, the use of a catalyst facilitates the dehydrogenation of linear paraffins to linear olefins having predominantly the same number

Figure 3. Simplified flow diagram for a combination of the UOP PACOL process and benzene alkylation
a) Pacol reactor; b) Separator; c) Stripper; d) Alkylation reactor

of carbon atoms (see also →Hydrogenation and Dehydrogenation).

The most important industrial process is the Pacol (paraffin catalyst olefin) process of Universal Oil Products (UOP). The reaction is carried out at 450 – 510 °C and 0.3 MPa using a hydrogen : carbon ratio of 9 : 1. A supported platinum catalyst, ca. 0.8 wt % Pt, on alumina, activated by addition of lithium and arsenic or germanium, is used. To minimize the formation of byproducts, especially aromatic hydrocarbons, which reduce catalyst activity, relatively low conversion rates of 10 – 15 % are used. This results in paraffin – olefin mixtures that are separated by means of the UOP Olex (olefin extraction) process. The Olex process employs molecular sieves, which absorb olefins more strongly than alkanes. The combination of both processes is known as the Pacol – Olex process [67]. In 1983, there were four Pacol – Olex plants worldwide, as well as 18 other plants where the Pacol process was combined with the alkylation of aromatics [68]. A simplified flow diagram of a Pacol benzene alkylation unit is shown in Figure 3.

Fresh *n*-alkane is added to the circulating paraffin, heated via heat exchangers, and dehydrogenated in the Pacol fixed-bed reactor (a) in the presence of hydrogen and at high throughput velocity. The products are separated into hydrogen and hydrocarbons in the separator (b) and volatile cracking products are removed in the stripper (c); these are then used chiefly as fuel. The stripper sump contains the higher linear monoolefins, which are reacted with benzene under acid catalysis to yield alkylbenzenes. The unreacted *n*-alkanes are returned to the Pacol reactor [69].

Chlorination – Dehydrochlorination. Another method for generating linear olefins from linear paraffins consists of chlorinating the paraffins to chloroalkanes, followed by a catalyzed second step in which hydrogen chloride is eliminated. Chlorination is carried out continuously in the liquid phase at 120 °C; the conversion is limited to a maximum of 30 %, to avoid excessive formation of dichlorides. A random mixture of linear olefins results from the dehydrohalogenation because the chlorine substituents are almost randomly distributed along the alkyl chain. The dehydrochlorination of chlorinated paraffins occurs in the presence of iron or iron alloy catalysts at 250 °C. The lower boiling olefins and paraffins are drawn off at the still head; the unreacted, higher boiling chlorinated paraffins remain in the reactor. Separating products in this manner requires that rather narrow cuts be taken, because the boiling points of the *n*-olefins and the chloroparaffins are quite close together [70, 71].

2.1.2.2. Oligomerization of Lower Olefins

All the methods described so far for the production of olefins from paraffins suffer from the disadvantage that crude oil containing linear paraffins with the required distribution of carbon atoms is in short supply. Several companies have, therefore, developed alternative routes to

Table 9. Composition of fractions (wt %) obtained from the Gulf process *

** Including traces of olefins with internal double bonds.

olefins that are based on oligomerization of olefins, especially of ethylene. Such starting materials are readily available from the pyrolysis of liquefied natural gas, naphtha, and gas oil fractions. The worldwide capacity for ethylene alone was ca. 50×10^6 t in 1983. Ethylene supplies appear assured for the forseeable future because it can be generated by the Mobil process from methanol, which is derived from coal-based synthesis gas.

The methods for buildup of longer chain olefins vary greatly. In the following sections syntheses via organoaluminum compounds, transition metal catalyzed oligomerization, and acid-catalyzed processes will be discussed.

Ethylene Oligomerization in the Presence of Organoaluminum Compounds. The first process for the industrial oligomerization of ethylene was discovered by ZIEGLER in the early 1950s [72]. The reaction proceeds in two stages: first a growth step followed by an elimination step.

$$AlEt_3 + 3nCH_2{=}CH_2 \longrightarrow Al[(CH_2CH_2)_nEt]_3$$

$$Al[(CH_2CH_2)_nEt]_3 + 3\,CH_2{=}CH_2 \longrightarrow AlEt_3 + 3\,CH_2{=}CH(CH_2CH_2)_{n-1}Et$$

The growth step occurs at ca. 100 °C under 10 MPa ethylene pressure. In the second stage, the high temperature displacement reaction, the alpha-olefins are displaced by ethylene at ca. 300 °C and 1 MPa. The composition of the product mixture corresponds to a Poisson distribution. This process suffers from the disadvantage of requiring stoichiometric quantities of reaction components, i.e., industrial plants would require large quantities of aluminum alkyls. Consequently, Gulf Oil and Ethyl Corporation developed two process variants that require less triethylaluminum.

The Gulf Oil Process. In the Gulf process, only catalytic quantities of triethylaluminum are used and growth step and elimination reactions occur simultaneously in the same reactor [73]. The reaction is carried out at <200 °C and ca. 25 MPa. The product mixture consists of a Schulz–Flory distribution of linear olefins. A typical composition of individual fractions from C_6-C_{18} is listed in Table 9.

The Gulf process produces markedly purer α-olefins than can be obtained with paraffin cracking (see Table 8). The major impurities in the α-olefins (trade name: Gulftenes) obtained by the Gulf process are ca. 1.4 % paraffins; with increasing carbon number, an increasing amount of β-branched α-olefin is also formed. The occurrence of these vinylidene and 2-ethyl compounds may be rationalized by consecutive reactions of α-olefins with the aluminum alkyls, as follows:

$$Al(CH_2CH_2R^1)_3 + 3\,CH_2{=}CH{-}R^2 \longrightarrow Al(CH_2\overset{\overset{R^2}{|}}{C}HCH_2CH_2R^1)_3 \xrightarrow{3\,CH_2{=}CH_2} AlEt_3 + 3\,CH_2{=}\overset{\overset{R^2}{|}}{C}{-}CH_2CH_2R^1$$

The Gulf Oil Co. uses the Gulf process to produce linear α-olefins in the C_4-C_{30} range at their plant in Cedar Bajou, Texas. Mitsubishi Chemical Industries uses the same process at Mizushima.

Ethyl Process. The Ethyl process combines a stoichiometric and a catalytic stage [74]. This modified Ziegler process is capable of controlling the chain length of the resulting α-olefins much more precisely, because the shorter chain olefins may be subjected to further chain growth.

The Ethyl process is illustrated schematically in Figure 4. Ethylene is first oligomerized using catalytic quantities of triethylaluminum in analogy to the Gulf process. The resulting products are fractionated (b) in Fig. 4) yielding fractions containing C_4, C_6-C_{10}, and $C_{12}-C_{18}$. The higher boiling fractions may be used directly,

Figure 4. Typical flow diagram of Ethyl process

Alkanes	0.1	0.6	0.3	0.4	0.4	0.4	0.8

whereas the shorter α-olefins, especially C_4, are subjected to transalkylation with long chain aluminum alkyls (c) in Fig. 4). This reaction releases the desired long-chain α-olefins; short-chain trialkylaluminum compounds are simultaneously formed. The aluminum trialkyls are separated in the second distillation step (Fig. 4, (d)) and transformed in another reactor (e) in Fig. 4) into longer chain alkyls by stoichiometric reaction with ethylene. The latter are then recycled to the transalkylation.

The Ethyl Corporation has operated a plant in Pasadena, Texas using this process since 1970; the initial capacity was 110 000 t/a. The process permits 95 % conversion of ethylene into higher α-olefins, a conversion efficiency not achievable by the single-step catalytic Gulf Oil process. This advantage is however, counterbalanced by a much lower product quality of the long-chain α-olefins. The C_{16}–C_{18} cut consists of only 63 % linear α-olefins (Table 10), the remainder being mainly β-branched α-olefins and internal olefins.

Ethylene Oligomerization with Transition-Metal Catalysis. In the presence of nickel, cobalt, titanium, or zirconium catalysts, ethylene may be converted into oligomers [75]. Commercial importance has been attained exclusively by the *Shell higher olefin process* (*SHOP*).

Shell Higher Olefin Process. The SHOP process is the most recent development in α-olefin synthesis. It works in the liquid phase using a nickel catalyst and yields α-olefins of unusually high purity [76–78]. Monoolefins are formed almost exclusively; analytical data indicate only trace amounts of dienes, aromatics, and alkanes. The content of α-olefin for the carbon numbers is in the range 96 – 97 %. A typical product composition is given in Table 11 (see next page).

The SHOP process involves a combination of three different reactions: *oligomerization, isomerization,* and *metathesis*. This integration of chain lengthening and shortening steps makes the SHOP process very flexible. Whereas all other α-olefin processes permit only limited control over product distribution, with the SHOP process it is possible to achieve almost any olefin cut desired. The SHOP process is shown schematically in Figure 5 [78–81].

Table 11. Composition of α-olefin fractions (wt %) obtained from the SHOP process

Figure 5. Typical flow diagram of SHOP process
a) Oligomerization reactor; b) Phase separator; c) Distillation; d) Isomerization reactor; e) Metathesis reactor

Oligomerization is carried out in a polar solvent such as ethylene glycol or 1,4-butanediol. The catalyst is produced in situ from a nickel salt, e.g., nickel chloride, sodium borohydride, and a chelating ligand. Suitable ligands are compounds of the general formula $RR^1P{-}CH_2{-}COR^2$, e.g., diphenyl phosphinoacetic acid, dicyclohexylphosphinoacetic acid, or 9-(carboxymethyl)-9-phosphabicyclo [3.3.1]- nonane. Ethylene is oligomerized to α-olefins with a Schulz – Flory distribution at 80 – 120 °C and 7 – 14 MPa. The olefins formed are immiscible with the polar solvent; product and catalyst phases are thereby readily separated so that the catalyst can be recycled repeatedly. Oligomerization is accomplished in a series of reactors interspersed with heat exchangers to remove the heat of reaction. The reaction rate can be regulated by the amount of catalyst. A high partial pressure of ethylene is required for high product linearity and a suitable rate of reaction. The chain length of the α-olefins is determined by the geometric factor K of molar growth:

$$K = \frac{n\,(C_{n+2}{-}\text{olefins})}{n\,(C_n{-}\text{olefins})}$$

where n is the number of moles.

The mass distribution of various α-olefins relative to the growth factor K is shown in Figure 6.

Figure 6. Product distribution as a function of growth factor K

Controlling the growth factor is extremely important for the overall process because K determines both the product distribution and the median chain length of the olefins obtained. It is, therefore, advantageous to be able to vary the K-factor by the composition of the catalyst.

After separation of the catalyst and product phase, the latter is washed with fresh solvent to remove the last traces of catalyst. In a subsequent distillation (see Fig. 5) the mixture is separated into the desired $C_{12} - C_{18}$ α-olefins and into low ($C_4 - C_{10}$) and high-boiling ($>C_{20}$) fractions. The $C_4 - C_{10}$ fraction can then be further fractionated, if desired, into individual compounds, for example, those used as comonomers for the manufacture of linear low density polyethylene (LLDPE). However, the $C_4 - C_{10}$ fraction and the $C \geq 20$ fractions are generally combined for isomerization and subsequent metathesis. These

two steps require only moderate reaction conditions: 80 – 140 °C, 0.3 – 2 MPa. The heat of reaction of both steps is quite low; because in isomerization only intramolecular migration of double bonds occurs, in metathesis carbon – carbon bonds are simultaneously cleaved and reformed. *Isomerization* takes place in the liquid phase in the presence of magnesium oxide catalyst [82]. About 90 % of the terminal olefins are converted to internal olefins in this reaction.

$$R-CH=CH_2 \xrightarrow{MgO} R^1-CH=CH-R^2$$

The subsequent joint *metathesis* of the internal, low, and high molecular mass olefins, mainly over heterogeneous rhenium or molybdenum catalysts, yields a mixture of internal olefins having a new chain length distribution, i.e., a random mixture of olefins of even and odd numbers of carbon atoms.

$$\begin{array}{c} R^1-CH=CH-R^2 \\ + \\ R^3-CH=CH-R^4 \end{array} \xrightarrow{\text{Re or Mo}} \begin{array}{c} R^1-CH \\ \| \\ R^3-CH \end{array} + \begin{array}{c} CH-R^2 \\ \| \\ CH-R^4 \end{array}$$

The products of metathesis are distilled and the $C_{11}-C_{14}$ fraction, representing ca. 10 – 15 % of the mixture, is separated for production of alcohols used in the detergent industry (see Section 2.1.3).

The composition of the internal $C_{11}-C_{14}$ olefins produced by the SHOP process is given in Table 12; more than 99.5 % is monoolefins, with only small amounts of dienes, aromatics, and paraffins.

Table 12. Composition of internal olefins (wt %) obtained from the SHOP process

Dienes	<0.1	<0.1
Aromatics	<0.1	<0.1
Paraffins	<0.5	<0.5

Although the double bonds of the olefins at the beginning of metathesis are distributed almost at random over the carbon backbone, they are shifted in the end product toward the chain end, a result of the high concentration of short-chain olefins (2-butene, 2-hexene, 3-hexene) in the metathesis feed.

Distillation of the metathesis products also yields low- and high-boiling components in addition to the $C_{11}-C_{14}$ fraction. One of the great advantages of the SHOP process is that these fractions do not have to be discarded but can be recycled. The fraction consisting of compounds with less than 11 carbon atoms is returned directly to the metathesis reactor; the fraction containing olefins with more than 14 carbon atoms is again subjected to isomerization before it reaches the metathesis stage. By combining oligomerization, isomerization, and metathesis, the SHOP process is capable of converting almost all the ethylene feed into olefins having the desired number of carbon atoms.

An interesting alternative of the SHOP process described above is the metathesis of the isomerized $C \geq 20$ fraction together with a ten-fold molar excess of ethylene [82]. Olefins, predominantly α-olefins, within the desired carbon range may be prepared in the presence of a rhenium catalyst (20 % Re_2O_7 on aluminum oxide).

$$\begin{array}{c} C_{10}H_{21}-CH=CH-C_{10}H_{21} \\ + \\ CH_2=CH_2 \end{array} \xrightarrow{Re_2O_7-Al_2O_3} 2\ C_{10}H_{21}CH=CH_2$$

The first SHOP processing plant was built in 1977 by Shell Oil Corporation at Geismar, Louisiana (see Section 2.1.4); annual capacity was 200 000 t.

The mechanism of the highly selective ethylene oligomerization with nickel chelate catalysts has been largely elucidated by the research group of W. Keim [76, 83–87]. A chelated nickel hydride complex is formed initially. This complex reacts with ethylene (Fig. 7, see next page) to form alkyl nickel complexes. Linear α-olefins are eliminated from the alkyl nickel complexes; the nickel hydride species is formed simultaneously to reenter the catalytic cycle.

The SHOP process is by far the most important method for oligomerization of ethylene involving transition-metal catalysts. To complete the picture, two other processes will be described below, although they have not yet reached commercial importance.

Figure 7. Mechanism of ethylene oligomerization in the presence of nickel P–O-chelate complex catalyst (for P–O ligand see text)

Exxon Process. The Exxon Corporation has developed a process in which ethylene is converted to high molecular mass olefins in the presence of a catalyst consisting of a transition-metal component and a soluble alkyl aluminum chloride [88]. Titanium chloride or an alkoxy titanium chloride are favored as the transition metal components. The catalyst is soluble in saturated hydrocarbons and active at 25 – 70 °C. This process yields linear α-olefins in the range C_4 – C_{100} or higher; it appears to be especially useful for the production of high-melting waxes, i.e., olefins higher than C_{20}.

Alphabutol Process. In the Alphabutol process, developed by the Institut Français du Pétrole (IFP), ethylene is selectively dimerized to 1-butene [89] using a homogeneous titanium catalyst. In contrast to the SHOP process, the mechanism does not involve metal hydrides but a titanium(IV) cyclopentane species that decomposes under the reaction conditions (50 – 60 °C, slight positive pressure) with β-hydrogen transfer to 1-butene:

The 1-butene, which contains only traces of impurities (hexenes, 2-butene, butanes) may be used as comonomer in the production of LLDPE.

Oligomerization of Propene and Butenes with Transition-Metal Catalysis. Ziegler catalysts consisting of nickel compounds and aluminum trialkyls can be used to dimerize or codimerize propene and butene to give predominantly branched olefins. This process was also developed by the Institut Français du Pétrole and is referred to as the Dimersol process [90–95]. IFP research began as early as the mid 1960s. The first commercial Dimersol-G plant was brought into production in 1977 by Total in Alma, Michigan. In the *Dimersol G process*, propene (in admixture with propane) is dimerized mainly (80 %) to isohexenes; small amounts of propene trimers (18 %) and tetramers (2 %) are also formed:

$$2\ C_3H_6 \longrightarrow$$

n-Hexenes + 2-methylpentenes + 2,3-dimethylbutenes

The reaction takes place in the liquid phase without solvent. The pressure in the reactor is adjusted so that the C_3 compounds remain liquid at the operating temperature. The product mixture leaving the reactor head is fed to a vessel where the catalyst is neutralized with alkali. The product (trade name: Dimate) is then washed with water and freed of any remaining propane and propene on a stabilizing column.

The *Dimersol X process* is similar, although the starting materials are butenes or a mixture of propene and butenes. The products formed are, accordingly, isooctenes or mixtures of C_6 – C_8 olefins. The first Dimersol X plant was started in 1980 by Nissan Chem. in Kashima, Japan. A typical starting material for the Dimersol X process is the raffinate II obtained from the C_4 cut of the steam cracker, after removal of butadiene and isobutene. The resulting C_8 olefins can be converted by Oxo-synthesis into nonanols, which are used for the synthesis of plasticizers (dinonyl phthalate).

A more recent development is the *Dimersol E* process, which employs the exhaust gases of fluid catalytic crackers (FCC) that contain ethylene and propene. A gasoline fraction can be obtained from this product after hydrogenation. The first experiments with cracker exhaust gases from the Elf cracker near Feyzin (France) began in 1984.

By 1982, IFP had licensed 16 Dimersol plants, eight of which were in production. In addition to IFP, other industrial and academic groups have investigated the transition metal-catalyzed oligomerization of lower olefins [96–104]. The observation that in the propene dimerization with nickel-based Ziegler catalysts the addition of phosphines may significantly affect the isohexene product distribution is of interest. With the catalyst $[NiBr(\eta^3\text{-}C_3H_5)(PCy_3)] - EtAlCl_2$ (Cy = cyclohexyl) a remarkable turnover of 800 000 mol propene per mol nickel h^{-1} could be achieved. A turnover of 60 000 s^{-1} was calculated for operation at room temperature. This value is of an order of magnitude usually achieved only by enzyme reactions.

Oligomerization of Propene and Butene by Acid Catalysis. Mineral acids such as phosphoric or sulfuric acid can also be used as catalysts for the oligomerization of olefins; the major products are branched olefins. Alkylbenzenes were once prepared from tetramers of propenes (tetrapropylene). This reaction is now rarely used in Europe because of the low biodegradability of the alkylbenzenesulfonates obtained.

Oligomerization of isobutene leads to the formation of diisobutene, triisobutene, and tetraisobutene; after hydrogenation, these may be added to gasoline to improve the octane rating (polymer gasoline, oligomer gasoline). In the *cold acid process*, isobutene-containing C_4 fractions are treated with 60 – 70 % sulfuric acid at room temperature. Isobutene dissolves in the sulfuric acid as *tert*-butyl sulfate. This solution is then oligomerized at 100 °C. The products, mainly diisobutenes, separate as a second phase. In the *hot acid process*, the *n*-butenes of the C_4 fraction are also converted, forming $i\text{-}C_4 - n\text{-}C_4$ cooligomers.

The oligomerization can also be performed with poly(styrene sulfonic acid) resins as catalysts. This process is used by Erdölchemie – Dormagen using the raffinate I (C_4 fraction after extraction of butadiene). The reaction is performed in loop reactors at 100 °C and 1.5 – 2.0 MPa with residence times of 20 – 60 min. The product is composed of 36 % diisobutene, 22 % C_8 codimers, 38 % triisobutene, and 4 % tetraisobutene. The product distribution may be changed by recycling specific fractions.

2.1.3. Uses of Higher Olefins

The most important uses of linear olefins are described below.

Synthesis of Oxo-Alcohols. Linear α-olefins can be converted to linear primary alcohols, which are used in the synthesis of plasticizers ($<C_{11}$) or detergents ($>C_{11}$) by hydroformylation (oxo synthesis). The reaction can also be used to give aldehydes as the major products.

$$R-CH=CH_2 \xrightarrow[\text{Cat.}]{CO,\ H_2} R-CH_2CH_2CH_2OH \text{ or } R-CH_2CH_2CHO$$

The yield of linear products can be increased to >90 % if phosphine-modified cobalt- or rhodium catalysts are used.

The described synthesis route for long-chain alcohols has strong competition, however, from the natural fatty alcohols and from the Alfoles, generated from ethylene by an organo aluminum synthesis with subsequent oxidation.

In the United States Monsanto has produced oxo alcohols from $C_6 - C_{10}$ α-olefins since 1971. Exxon has used the oxo process since 1983 to produce plasticizer alcohols in the $C_7 - C_{11}$ range at Baton Rouge, Louisiana. Shell also converts olefins to alcohols. In recent years, olefins derived from paraffin crackers as starting materials have been replaced by internal olefins from the SHOP process.

The possibility of converting olefin-derived aldehydes to short-chain synthetic fatty acids by oxidation is also notable:

$$R-CH_2CH_2CHO \xrightarrow{\text{Oxid.}} R-CH_2CH_2COOH$$

In 1980 Celanese (now Hoechst-Celanese) built a plant in Bay City, Texas with an annual capacity of 18 000 t to produce heptanoic and nonanoic acids from 1-hexene and 1-octene, respectively, which are used in the production of lubricants. Again, there is strong competition from the natural products, which are generally less expensive. In addition, lubricant production requires highly linear acids. Fatty acids from

oxo aldehydes have a linearity of >95 %; natural fatty acids have a linearity of almost 100 % (→Fatty Acids).

Synthesis of Linear Alkylbenzenes. Currently the most important class of detergents for domestic use is still the linear alkylbenzenesulfonates (LAS or LABS). They are prepared by Friedel–Crafts reaction of benzene with linear olefins followed by sulfonation:

Total estimated production of LAS in Western Europe, Japan, and the United States in 1982 was ca. 1.1×10^6 t. In Europe, Asia, South Africa, and South America linear alkylbenzenes are produced from $C_{10}-C_{15}$ *alpha*-olefins. In 1982, 420 000 t of LAB were synthesized in Western Europe from ca. 80 000 t of linear olefins.

Synthesis of α-Alkenesulfonates. α-Alkene sulfonates (α-olefin sulfonates, AOS or OS) are obtained by direct sulfonation of $C_{14}-C_{18}$ α-olefins (→Detergents). An ionic mechanism results in a product mixture of 40 % isomeric alkenesulfonic acids (with the double bond predominantly in the β- or the γ-position) and 60 % 1,3- or 1,4-alkanesulfones. Following hydrolysis with sodium hydroxide, a mixture of alkenesulfonates and hydroxyalkanesulfonates is obtained:

The double bonds and the hydroxyl groups contribute to the excellent water solubility of the AOS compounds. They are effective laundry agents even in hard water and at low concentration and are used increasingly in liquid soaps and cosmetics. In order to be used in such products the AOS must be of high quality, especially with regard to color; this is only possible with α-olefins that contain no more than traces of dienes.

Although AOS compounds have been known since the 1930s, they gained commercial importance only in the late 1960s. In 1982, ca. 7000 t of AOS were produced in the United States from α-olefins, with the Stepan Company and Witco Chemical Corporation being the largest U.S. producers. AOS represents an interesting alternative to alkyl sulfates and alkyl ether sulfates in cosmetic products.

Synthesis of Bromoalkanes and Derived Products. An important reaction of α-olefins is radical hydrobromation to give primary bromoalkanes. These compounds are valuable intermediates for, e.g., thiols, amines, amine oxides, and ammonium compounds:

Thiols are produced by this route in Europe and in the United States by Pennwalt Corp. and Phillips Petroleum Co. They are used in the synthesis of herbicides, pesticides, pharmaceuticals, in the textile industry, or as polymer regulators.

In 1982, ca. 15 000 t of alkyldimethylamine (ADA) was produced from linear α-olefins in the United States by Ethyl Corporation and by Procter & Gamble. Most of these amines were directly converted to fatty amine oxides (FAO) or quaternary ammonium salts (Quats). Fatty amine oxides are nonionic surfactants that, because they are biodegradable and do not irritate the skin, are incorporated into numerous products, e.g., into rinsing agents. Quats are produced by alkylation of amines, e.g., with benzylchloride. Benzyl-Quats possess biocidal and antimicrobial properties and are incorporated,

for example, into disinfectants and deodorants (→ Laundry Detergents).

Production of Synthetic Lubricants (→Lubricants and Related Products). Oligomerization of α-olefins in the middle C-number range, in particular 1-decene, to isoparaffins (mostly trimers with a few tetramers and pentamers) leads to lubricants known as poly(α-olefins) (PAO) or synthetic hydrocarbons (SHC). They are used industrially, and in the automobile and aircraft sectors [105, 106]. They are in many instances superior to natural mineral oils, especially at lower temperature, because of their favorable viscosity, low volatility, high flash point, and high thermal stability. Oligomerization of the α-olefins can be performed with, e.g., BF_3, to which protonic cocatalysts, e.g., water or alcohols, are added.

In 1982, ca. 25 000 t of PAO were produced in the United States. The major producers are Mobil Oil, Gulf Oil, National Distillers, Burmah-Castrol, and Ethyl Corporation.

Production of Copolymers. Linear α-olefins, in particular 1-butene, 1-hexene, and 1-octene, are used as comonomers in the production of high density polyethylene (HDPE) and linear low density polyethylene (LLDPE). By adding α-olefins the density and other properties of the polymers may be significantly modified. HDPE copolymers contain only relatively small quantities of α-olefins, generally 0.5 – 3 %. The density of the HDPE homopolymer (0.965 – 0.955 g/cm^3) is reduced to 0.959 – 0.938 g/cm^3 for the HDPE copolymer. The most frequently employed comonomer is 1-hexene, followed by 1-butene.

On the other hand, 4 – 12 % α-olefin is generally added to LLDPE to reduce the density to 0.935 – 0.915. The more α-olefins added to the polymer, the greater the number of short-chain branches and the lower the density. Addition of 1-butene is preferred in many of the gas-phase processes, e.g., in the Unipol process introduced by Union Carbide in 1977 [107], whereas 1-octene and 1-hexene are preferred in liquid-phase processes.

Major United States producers are Dow Chemical, DuPont, Exxon, Gulf Oil, Union Carbide, Soltex Polymer Corporation, Phillips Petroleum Company, and Allied Corporation. An estimated 85 000 t of α-olefins were copolymerized in HDPE and LLDPE in the United States in 1982.

Because Shell began marketing SHOP olefins in Western Europe, the use of HDPE and LLDPE copolymers has increased in these countries. Olefins derived from paraffin cracking plants are unsuitable as comonomers for polyethylene because of the impurities they contain.

Additional Reactions of α-Olefins. The reaction of α-olefins with peracid to form epoxides is an interesting route to bifunctional derivatives [108]. Some examples are given below (see also →Epoxides, Chap. 2.1.).

α-Olefin epoxides have also been used in polymer chemistry, e.g., for the modification of epoxy resins. United States producers of α-olefin epoxides include: Union Carbide, Viking, and Dow Chemical.

Another use of α-olefins is conversion into secondary monoalkylsulfates, which are readily degradable surfactants useful in wetting agents and household detergents. They are synthesized by reaction with concentrated sulfuric acid at low temperature (10 – 20 °C) and with short reaction times (5 min):

Hydrocarboxylation of α-olefins leads to odd-numbered carboxylic acids. This reaction is carried out with carbon monoxide and water at

Table 13. Linear α-olefin producers (January 1984)

Manufacturer	Location	Process	Annual capacity (10^3 t)
Gulf Oil	Cedar Bayou, Texas	Oligomerization (Gulf process)	90
Mitsubishi	Mizushima, Okayama	Oligomerization (Gulf process)	30
Ethyl Corp.	Pasadena, Texas	Oligomerization (Ethyl process)	450

Shell	Berre (France)	Paraffin cracking	90
	Pernis (The Netherlands)	Paraffin cracking	170
	Geismar, Louisiana	SHOP	270
	Stanlow (UK)	SHOP	170
		Total	1310

200 °C and 20 MPa. The formation of linear carboxylic acids is favored in the presence of cobalt carbonyl – pyridine catalysts. Both the free acids and their esters are used as lubricant additives.

$$R-CH=CH_2 \xrightarrow[Co]{CO,\ H_2O} R-\underset{\underset{COOH}{|}}{CH}-CH_3 + R-CH_2CH_2COOH$$

The alkenylsuccinic anhydrides (ASA) should also be mentioned. They are obtained by heating maleic anhydride with α- or internal olefins, and are used as lubricant additives, detergents, and in leather and paper production. Olefins with more than 30 carbon atoms are waxy and can be used as paraffin substitutes. In 1984 ca. 8000 t of α-olefins were used in the United States for the production of candles, crayons, and coatings.

2.1.4. Economic Aspects of Higher Olefins

Production facilities for α-olefins and their capacities (1984) are listed in Table 13.

The α-olefin market has been subject to fluctuations [109]. Ethyl Corporation, the largest United States α-olefin producer, announced at the end of 1987 the intention to build a large α-olefin plant in Europe with an annual capacity of 250 000 t [110]. This plant would make Ethyl the largest α-olefin producer in Europe.

Shell has also been planning for some time to expand its SHOP processing capacity. The SHOP plant in Geismar, United States, which has been operating since 1977, was expanded in 1982 to an annual capacity of 270 000 t. Construction of a second SHOP unit in Geismar had been announced for 1984 [111]. According to [112], this second plant should come on stream in 1989 with an annual capacity of 243 000 t. Additional expansion is to bring the total annual capacity at Geismar to 590 000 t.

Shell has also announced changes in Europe [113]. The plant at Stanlow, United Kingdom, operating since 1982, is to be expanded to an annual capacity of 220 000 t; once this plant is fully operational, the plant at Pernis, The Netherlands which for some time has produced only 60 000 – 70 000 t/a, is to be closed down.

Mitsubishi Petrochemical has expressed an interest in constructing a SHOP plant in Kashina, Japan in a joint venture with Shell [114]. Other projects under discussion are SHOP plants in New Zealand and in Canada [115].

Uses of linear olefins in the United States and in Western Europe are given in Table 14.

Table 14. Uses of higher linear olefins (1982) (estimate by the Stanford Research Institute)

Final products	Olefin consumption (10^3 t)	
	United States *	Western Europe
Oxo alcohols	67	145 – 160
Amines and derivatives	13 – 17	**
α-Olefinsulfonates (AOS)	7	3
Linear alkylbenzenes (LAB)	1 – 2	75 – 80
Copolymers (HDPE, LLDPE)	85	**
Synthetic lubricants (SHC)	25	**
Lubricant additives	15	20

* Figures refer exclusively to α-olefins.
** Unknown.

2.2. Dienes and Polyenes

2.2.1. Low Molecular Mass 1,3-Dienes

Industrially, the most important 1,3-dienes are butadiene, isoprene, and cyclopentadiene

(→Butadiene; →Cyclopentadiene and Cyclopentene; →Isoprene). The conjugated dienes listed below are of lesser importance.

Piperylene (1,3-pentadiene) is present at a level of >10 % in the C_5 steam cracker fraction; it is expensive to separate from the C_5 cut. Polymers and copolymers with, for example, butadiene have been produced but have not yet found a technical application.

2,3-Dimethylbutadiene was the first monomer to be converted on an industrial scale to a synthetic rubber, referred to as methyl rubber. It was developed by HOFFMANN in 1910 and produced during 1914 – 1918. It suffered, however, from several disadvantages (excessive hardness, sensitivity to oxidation) and later lost its importance. The early synthesis of the monomer involved conversion of acetone to pinacol, which is then dehydrogenated to the diene in the presence of aluminum oxide as catalyst. Modern synthesis starts with propene, which is dimerized to 2,3-dimethylbutene [103, 104] and subsequently dehydrogenated:

Chloroprene (→Chlorinated Hydrocarbons, Chap. 6.4.), $CH_2{=}CCl{-}CH{=}CH_2$, 2-chloro-1,3-butadiene, is used to form polychloroprene (neoprene), which is extremely resistant to oil, abrasion, and ageing. As with all polymers containing a large proportion of halogen, these products are resistant to ignition. Vulcanized polychloroprene is used in, for example, conveyer belts, cable shielding, and protective clothing. Nonvulcanized polymers are used as contact adhesives in plastics manufacturing.

Chloroprene can be produced by two routes. In the older process, acetylene is first dimerized to vinyl acetylene and hydrogen chloride then added to the triple bond; both steps take place in the presence of CuCl as catalyst. The second process involves chlorination of butadiene, at 300 °C with chlorine to yield a mixture of dichlorobutenes. The 1,2-adduct is subsequently dehydrochlorinated to yield chloroprene. The 1,4-adduct can be isomerized to the 1,2-adduct:

2.2.2. Synthesis of Dienes and Polyenes by Oligomerization

A multitude of linear and cyclic dienes and polyenes can be synthesized by transition metal-catalyzed oligomerization or by cooligomerization [75]. Only a few examples will be described below, some of which are used commercially. Butadiene can be converted into six cyclooligomers in a nickel-catalyzed reaction [116]. The synthesis can be steered in the desired direction by a suitable choice of catalyst.

1,5-Cyclooctadiene is produced by Shell and by Hüls and is used, for example, as starting material for suberic acid and poly(octenamer) (→Cyclododecatriene, Cyclooctadiene, and 4-Vinylcyclohexene).

1,5,9-Cyclododecatriene is produced by DuPont, Shell, and Hüls using nickel or titanium as catalyst; it is used in the synthesis of nylon 12, dodecandioic acid, and hexabromocyclododecane.

4-Vinylcyclohex-1-ene is also accessible from butadiene but is, as yet, of little commercial importance. The possibility of using it as a precursor in styrene synthesis has been discussed.

An example of catalytic cooligomerization is the reaction between butadiene and ethylene [117].

Whereas the cyclic 1 : 1 product vinylcyclobutane and the C_{10} oligomers cyclodecadiene and 1,4,9-decatriene are not yet used commercially, the linear oligomer, 1,4-hexadiene, is produced as a monomer for the production of ethylene – propene – diene (EPDM) elastomers. Homogeneous catalysis with rhodium or palladium complexes leads to *trans*-1,4-hexadiene; cobalt and iron catalysts yield predominantly the *cis*-1,4-product. Rhodium catalysts are used in commercial production.

Ethylidenenorbornene, also a comonomer for EPDM polymers, is also accessible via cooligomerization. One of the routes employs the Diels – Alder reaction starting with butadiene and cyclopentadiene, the other couples norbornadiene and ethylene in the presence of a nickel catalyst. Vinylnorbornene is formed as an intermediate in both routes.

2.2.3. Synthesis of Dienes and Polyenes by Metathesis

Metathesis offers a simple path to α,ω-diolefins that are not easily obtained by other routes [118]. Starting materials are cycloolefins, which can be prepared, for example, by cyclooligomerization of butadiene (see Section 2.2.2) and subsequent partial hydrogenation. Metathetic conversion with ethylene opens the cycloolefin to an α,ω-diene. In this manner, 1,5-cyclooctadiene gives two molecules of 1,5-hexadiene; cyclooctene forms 1,9-decadiene; and cyclododecene leads to 1,13-tetradecadiene.

Heterogeneous rhenium catalysts are preferred because they allow the reaction to proceed under very mild conditions (5 – 20 °C, 0.1 – 0.2 MPa ethylene). A plant with an annual capacity of 3000 t using this FEAST (Further Exploitation of Advanced Shell Technology) process was brought on stream by Shell in Berre (France) in 1987. The products are suitable for the synthesis of numerous fine chemicals, e.g., production of long-chain diketones, for dibromides, diepoxides, dialdehydes, dithiols, and diamines.

4-Vinylcyclo-1-hexene undergoes self metathesis. Elimination of ethylene yields 1,2-bis(3-cyclohexenyl)ethylene, which has been used as a starting material for fire retardants.

3. Alkylbenzenes

Toluene, Xylenes, and Ethylbenzene are separate keywords.

Table 15. Physical properties of alkylbenzenes [119]

Compound	CAS registry number	M_r	*mp*, °C	*bp*, °C	d_4^{20}, g/cm^3	n_D^{20}

[e] At 19 °C.
[f] At 130 °C.

3.1. Trimethylbenzenes

Properties. The three isomers of trimethylbenzene are colorless liquids. Some of their physical properties are listed in Table 15.

1,2,3-Trimethylbenzene
Hemimellitene

1,2,4-Trimethylbenzene
Pseudocumene

1,3,5-Trimethylbenzene
Mesitylene

The methyl groups of trimethylbenzenes are converted to carboxyl groups on oxidation. Dilute nitric acid oxidizes mesitylene to the corresponding tricarboxylic acid, trimesic acid [*554-95-0*]. In pseudocumene the preferred site of reaction for halogenation, sulfonation, and nitration is the 5-position; disubstitution leads to 3,5-derivatives. Mild oxidation of pseudocumene or mesitylene, with manganese- or lead dioxide, or electrolytically, leads to 2,4- or 3,5-dimethylbenzaldehyde, respectively.

Production. Hemimellitene, pseudocumene, and mesitylene are found in coal tar oil. The compounds can be isolated by distillation and purified by the differential hydrolysis of their sulfonic acids [120]. More important industrially is the occurrence of trimethylbenzenes in some mineral oils, and their formation during processing of crude oil, especially catalytic cracking and reforming. Pseudocumene is obtained in 99 % purity by superfractionation from the C_9 cut of crude oil refining [121]. Pseudocumene and hemimellitene can be obtained by extractive crystallization of the C_9 cut with urea [122]. Trimethylbenzenes can be produced by Friedel – Crafts methylation of toluene or xylene with chloromethane in the presence of aluminum chloride. Trimethylbenzenes, especially pseudocumene and mesitylene, are also formed by liquid-phase disproportionation of xylene in the presence of aluminum chloride. These reactions can be carried out in the gas phase at high temperature on aluminum silicate catalysts.

A more recent method for the methylation of xylene with methanol or dimethyl ether on fluorine-containing crystalline borosilicate, aluminosilicate, or boroaluminosilicate (ZSM-5) at 300 °C and atmospheric pressure yields pseudocumene and durene almost exclusively, both of which may be isolated at >99 % purity [123]. Trimethylbenzenes are also generated in the reaction of toluene with synthesis gas over a dual catalyst consisting of a metal oxide component and an aluminum silicate, at 200 – 400 °C and up to 20 MPa [124]. Pseudocumene is also generated from methanol as a byproduct of the Mobil MTG (methanol to gasoline) process (see Section 3.2). Fusel oils and other fermentation products may be reacted on the zeolite catalyst HZSM-5 to form aromatic compounds, including trimethylbenzenes [125].

Uses. Mesitylene is used in the synthesis of dyes and antioxidants, and as a solvent. Pseudocumene is a starting material for dyes, pharmaceuticals and, especially, for trimellitic anhydride [*552-30-7*], which is then converted to heat-resistant polyamideimides and polyesterimides (see also Carboxylic Acids, Aromatic, Chap. 4.3.). Hemimellitene is an intermediate in the production of fragrances (→ Flavors and Fragrances).

3.2. Tetramethylbenzenes

Properties. Some physical properties of the three tetramethylbenzene isomers are listed in Table 15. Prehnitene and isodurene are colorless liquids; durene forms colorless, monoclinic crystals that sublime slowly at room temperature and that have an odor reminiscent of camphor.

1,2,3,4-Tetramethylbenzene
Prehnitene

1,2,3,5-Tetramethylbenzene
Isodurene

1,2,4,5-Tetramethylbenzene
Durene

Tetramethylbenzenes are readily soluble in aromatic hydrocarbons, acetone, ether, and alcohol. Durene is highly reactive; nitration, chlorination, sulfonation, and chloromethylation occur almost as readily as with phenol. The methyl groups may be successively oxidized to carboxylic acids; the presence of the corresponding mono-, di-, tri-, and tetracarboxylic acids can be demonstrated during liquid-phase oxidation of durene in the presence of cobalt catalyst [126].

Production. The tetramethylbenzenes also occur in coal tar from anthracite and lignite, and in the reformed fraction of oil refineries. The isolation of durene by crystallization is aided by its relatively high melting point; isodurene becomes enriched in the mother liquor. Methylation of xylene leads to an isomeric mixture, from which durene, prehnitene, and isodurene can be obtained [120]. Durene is produced by liquid-phase methylation of pseudocumene with chloromethane in the presence of aluminum chloride [127]. In more recent processes durene is produced by reaction of xylene or pseudocumene with methanol in the gas phase over aluminum silicates; the most successful process uses the zeolites ZSM-5 and TSZ [128, 129]. In the MTG process, commercialized in New Zealand since 1986, the production of automotive fuels from methanol over ZSM-5 yields an unacceptable quantity of durene, which has to be removed from the fuel to avoid carburetor clogging by the high melting point impurity. The durene is currently removed by catalytic isomerization, disproportionation, and reductive demethylation. The possibility of isolating durene from the MTG process is being investigated [130].

Uses. Oxidation of durene leads to the commercially important pyromellitic dianhydride [*89-32-7*] used as a starting material for heat-resistant polyimides (→Polyimides) and as a hardener for epoxy resins (→Epoxy Resins). Pyromellitic esters serve as migration-resistant plasticizers for poly(vinyl chloride) (→Carboxylic Acids, Aromatic, Chap. 4.2.).

3.3. Penta- and Hexamethylbenzene

Properties. Some physical properties are listed in Table 15. Both compounds are crys-

talline at room temperature; they dissolve easily in benzene and ethanol. The methyl groups are readily oxidized to carboxyl groups. Irradiation with light converts hexamethylbenzene into its valence isomer hexamethyl Dewar benzene (1,2,3,4,5,6-hexamethylbicyclo [2.2.0] hexa-2,5-diene, [*7641-77-2*]). Electrophilic substitution on the free ring site of pentamethylbenzene proceeds readily.

Production. Penta- and hexamethylbenzene are generated by liquid-phase Friedel – Crafts alkylation of xylene or pseudocumene with chloromethane in the presence of aluminum chloride [127]. If the reaction is carried out at 140 – 180 °C in *o*-dichlorobenzene, hexamethylbenzene with a purity of 98 % can be crystallized directly from the reaction mixture [131]. In a more recent method, penta- and hexamethylbenzene can be produced simultaneously by reaction of phenol and methanol in toluene in the presence of a zinc aluminate catalyst at 330 – 360 °C [132]. The products are then separated by fractional crystallization. Hexamethylbenzene is formed by thermal rearrangement of hexamethyl Dewar benzene, which is readily obtained from 2-butyne [133].

Uses. Pentamethylbenzene is of little commercial importance. Hexamethylbenzene is an intermediate in the fragrance industry. It is of scientific interest in studies of charge transfer complexes and exciplexes, in which, like other methylbenzenes, it may function as donor [134].

3.4. Diethylbenzenes

Properties. For some physical properties see Table 15.

Production. The three isomeric diethylbenzenes (DEB) occur as byproducts in the production of ethylbenzene from benzene and ethylene but are, generally, recycled to undergo transalkylation (→Ethylbenzene). In the liquid-phase Friedel – Crafts process with aluminum chloride an increase in the feedstock ratio of ethylene to benzene may raise the DEB concentration in the output to 35 %. The DEB fraction consists of ca. 65 % 1,3-DEB, 30 % 1,4-DEB, and only 5 % 1,2-DEB. A similar isomer distribution is found in the product mixture from gas-phase alkylation of ethylbenzene with ethylene on an unmodified HZSM-5 zeolite catalyst. By modifying the catalyst, the zeolite pore may be narrowed to such an extent that, based on geometry alone, only 1,4-diethylbenzene is formed, rather than the bulkier 1,2- and 1,3-isomers. The Mobil gas-phase alkylation, which is based on such a shape-selective zeolite, converts ethylbenzene to DEB at 400 °C and 0.7 MPa with 88 % selectivity; more than 99 % of the DEB is the 1,4-isomer [135]. Nearly quantitative formation of 1,3-DEB occurs at low temperature in the liquid phase by disproportionation of ethylbenzene in the presence of at least 10 vol % HF and 0.3 – 0.5 mol BF_3 per mol ethylbenzene.

Uses. Diethylbenzenes may be converted to divinyl benzenes by catalytic dehydrogenation (→Hydrogenation and Dehydrogenation). The latter are useful in the production of cross-linked polystyrenes. DEB is contained in the product of the MTG process (see Section 3.2) and improves the properties of the gasoline.

3.5. Triethylbenzenes and more highly Ethylated Benzenes

Properties. For some physical properties see Table 15.

Production. The more highly ethylated benzenes are produced in the liquid phase in a similar manner as that described for diethylbenzene. 1,3,5-Triethylbenzene may be generated in excellent yield by disproportionation of diethylbenzene with BF_3 and HF at 75 °C. The same result is obtained with $AlCl_3$ – HCl as catalyst. 1,3,5-Triethylbenzene is also formed by cyclocondensation of 2-butanone in the presence of sulfuric acid. Hexaethylbenzene is formed in nearly quantitative yield when ethylene is passed into the $AlCl_3$ complex of aromatics until a mass

of crystals is formed, which is then worked up with water.

3.6. Ethylmethylbenzenes (Ethyltoluenes)

Properties. Some physical properties are collected in Table 15.

Production. Ethyltoluene is produced in similar fashion to ethylbenzene, i.e., by ethylation of toluene. Alkylation of toluene with ethylene in the presence of $AlCl_3$ and HCl gives all three isomers of ethyltoluene and more highly ethylated derivatives. A typical reaction mixture contains 48 % unreacted toluene, about 12 % 4-ethyltoluene, 19 % 3-ethyltoluene, 4 % 2-ethyltoluene, 14 % higher aromatics, and barely 1 % tar [135]. According to a Dow process, subsequent distillation gives a mixture of 3- and 4-ethyltoluenes [136]. 2-Ethyltoluene, toluene, and the more highly alkylated toluenes are then recycled. The gas-phase ethylation of toluene on unmodified HZSM-5 zeolite catalyst at 350 °C gives 23 % 4-ethyltoluene, 53 % 3-ethyltoluene, 8 % 2-ethyltoluene, and 10 % higher aromatics [137]. Formation of the 2- and 3-isomers in the ethylation of toluene can be almost completely suppressed by the use of a shape-selective ZSM-5 zeolite that has been modified by addition of phosphorus, boron, or other elements, and by suitable physical treatment. In a Mobil process, 4-ethyltoluene of 97 % purity is generated in this manner at 350–400 °C [137]. A patent granted to Universal Oil Products claims a process for the production of an alkylbenzene mixture, which also contains ethyltoluene, from toluene and synthesis gas [124].

Uses. The mixture of 3- and 4-ethyltoluene obtained by the Dow process is catalytically dehydrogenated to the corresponding mixture of methylstyrenes, known commercially as vinyltoluene [*25013-15-4*], and then polymerized to "poly(vinyltoluene)." Dehydrogenation of the practically pure 4-ethyltoluene from the Mobil process to 4-methylstyrene [*622-97-9*] occurs analogously on the route to "poly(*p*-methylstyrene)". A plant for the alkylation of toluene to 4-ethyltoluene by the Mobil process was opened in 1982 by Hoechst (now Hoechst-Celanese) in Baton Rouge, Louisiana [138]; the plant has an annual capacity of 16 000 t of 4-methylstyrene and has been purchased by Deltech in 1989. The output of the two products vinyltoluene and *p*-methylstyrene is estimated at 25 000 t/a [139] (→Polystyrene and Styrene Copolymers).

3.7. Cumene

Properties. Cumene [*98-82-8*], 2-phenylpropane, isopropylbenzene, C_9H_{12}, M_r120.19, is a colorless, mobile liquid with a characteristic, aromatic odor.

Cumene

The effect of cumene in increasing the octane rating of motor fuels (→Octane Enhancers) has long been known. Large plants for production of cumene, which was used as a component of aviation fuel, were constructed in the United States during the early 1940s. Some physical properties of cumene are listed below [140, 141]:

mp, °C	−96.04
bp, °C	152.39
d^{20}. g/cm^3	0.86179
n_D^{20}	1.49145
Specific heat (25 °C), J g^{-1} K^{-1}	1.96
Heat of vaporization, kJ/mol	
at 25 °C	44.23
at 152.4 °C	37.74
T_{crit}, K	631
p_{crit}, MPa	3.21
V_{crit}, cm^3/mol	428
Flash point, °C	43
Ignition temperature, °C	425

The variation of vapor pressure with temperature is given below:

t, °C	2.9	38.3	66.1	88.1	129.2
Vapor pressure, kPa	0.13	1.33	5.33	15.33	53.33

For more thermodynamic data, see [142]. Explosion limits for the system cumene vapor – oxygen – nitrogen at standard pressure and at 0.56 MPa are given in [143]. For cumene – air mixtures the explosion limits are 0.8 – 6.0 vol % cumene, corresponding to a cumene

concentration of 40 – 300 g/m^3 [144]. Cumene forms azeotropes with water, aliphatic carboxylic acids, ethylene glycol ethers, cyclohexanol, and cyclohexanone.

Production. Cumene is produced from benzene [*71-43-2*] and propene [*115-07-1*] in the presence of an acidic catalyst:

$$C_6H_6 + C_3H_6 \longrightarrow C_6H_5CH(CH_3)_2 \quad \Delta H = -113\ \text{kJ/mol}$$

Two processes are employed industrially (see also→ Acylation and Alkylation). In the *UOP process* a fixed bed consisting of polyphosphoric acid on a silica support is used as the catalyst [145]. The reaction takes place mainly in the gas phase at ≥200 °C and ≥2 MPa. Pure propene or propene with a propane content ≥5 % is used as raw material, together with benzene (min. purity 99.5 %) in up to 12-fold molar excess; this leads to high distillation costs in the product work-up. The yield of cumene is 97 % based on benzene and 90 % based on propene [146]. The losses are caused by overalkylation and oligomerization of the propene. The high-boiling residue contains 50 – 60 % diisopropylbenzenes (*o*- : *m*- : *p*- ratio 1 : 2 : 2 – 3) and numerous other byproducts. It is not possible to recycle these products to the alkylation reactor, because polyphosphoric acid has no transalkylation properties.

The *second industrial process* works in the liquid phase at 50 – 80 °C; aluminum chloride or the liquid double compound formed from aluminum chloride, (isopropyl-)benzene, and hydrogen chloride is employed as the catalyst. This complex is separated from the product stream, as a heavy phase and is returned to the alkylation reactor. Except for a small purge stream higher alkylated byproducts are recycled to the alkylation step, whereby essentially complete use of both benzene and propene bound in di- and triisopropylbenzenes is achieved by transalkylation. The yield of cumene, referred to benzene and propene, is 99 % and 98 %, respectively. The UOP process is used predominantly. Higher selectivity and the lower energy requirements, however, are now making the aluminum chloride process more attractive [146].

Uses. The production capacity for cumene in Western Europe, the United States, and Japan amounts to 2×10^6, 2×10^6, and 4×10^5 t/a, respectively. Cumene is used almost exclusively for the production of phenol [*108-95-2*] and acetone [*67-64-1*] (→Acetone, Chap. 4.1.; →Phenol). This process is based on the discovery in 1944 that cumene hydroperoxide [*80-15-9*], obtained by oxidation of cumene with oxygen, can be cleaved under the catalytic action of strong acids:

$$C_6H_5CH(CH_3)_2 + O_2 \longrightarrow C_6H_5C(CH_3)_2OOH$$

$$C_6H_5C(CH_3)_2OOH \longrightarrow C_6H_5OH + CH_3COCH_3$$

Both reactions are exothermic; the enthalpy of reaction amounts to 121 and 255 kJ/mol, respectively. (For cumene quality specifications, see Acetone, Chap. 4.)

Pure α-methylstyrene can be obtained as a byproduct of the phenol process. Cumene hydroperoxide is used as a radical initiator for the copolymerization of styrene with butadiene and acrylates, and also for the radical cross-linking of unsaturated polyester resins. Addition of cumene hydroperoxide to α-methylstyrene gives dicumyl peroxide, used for radical cross-linking of polyolefins. Hydrogenation of the aromatic nucleus in cumene gives isopropylcyclohexane (hydrocumene), a cycloaliphatic solvent with a high boiling point (154.5 °C) and a low freezing point (−90 °C).

3.8. Diisopropylbenzenes

1,4-Diisopropylbenzene [*100-18-5*] *p*-diisopropylbenzene, *p*-DIPB, $C_{12}H_{18}$, M_r162.26, 1,3-diisopropylbenzene [*99-62-7*], *m*-diisopropylbenzene, *m*-DIPB, and mixtures of these isomers, are industrially important. Some physical properties of diisopropylbenzenes are given in Table 16.

Table 16. Physical properties of diisopropylbenzene isomers [140]

Property	*m*-DIPB	*o*-DIPB	*p*-DIPB
CAS registry number	[*99-62-7*]	[*577-55-9*]	[*100-18-5*]
mp, °C	−63.13	−56.68	−17.07
bp, °C	203.18	203.75	210.35
d^{20}, g/cm^3	0.8559	0.8779	0.8568
η_D^{20}	1.4883	1.4960	1.4893

p-DIPB

m-DIPB

The flash point of DIPB mixtures is 77 °C; the ignition temperature is 449 °C. Inhalation of DIPB vapor can lead to the appearance of narcotic effects.

Production. Diisopropylbenzenes are present in the high boiling fractions, in which they may account for 50 – 70 wt %, of cumene plants, together with numerous other byproducts. Processes for the production of *m*- and *p*-DIPB from these fractions have been suggested [147, 148]. The high-boiling fraction of the aluminum chloride process frequently contains 1,1,3-trimethylindan [*2613-76-5*], *bp* 204.8 – 204.9 °C, which cannot be separated from the *m*- and *p*-DIPB at a justifiable cost.

For production from benzene and propene alkylation catalysts that possess high isomerization and transalkylation activities are employed. Examples include aluminum chloride – hydrogen chloride [149, 150], silica – alumina [151, 152], boron trifluoride-treated alumina [153], and zeolithes [154]. The process is controlled in such a way that cumene formed at a later stage is alkylated with propene. The desired DIPB isomer is isolated by distillation and the undesired DIPB isomer, together with triisopropylbenzenes, are converted to cumene by reaction with benzene in a transalkylation step. The aim in both the alkylation and the transalkylation steps is to reach thermodynamic equilibrium, at which the *o*-diisopropylbenzene is present at only ca. 0.1 %.

Uses. 1,3-Diisopropyl- and 1,4-diisopropylbenzene are the starting materials for new synthetic routes to resorcinol (→Resorcinol) and hydroquinone (→Hydroquinone), respectively [155], which are used industrially in Japan and the United States [152]. Furthermore, a process for the production of phloroglucin, 1,3,5-trihydroxybenzene, from 1,3,5-triisopropylbenzene has been developed [156]. The monohydroperoxides of 1,3- and 1,4-diisopropylbenzene are used as initiators for the thermal cross-linking of unsaturated polyester resins, and for the emulsion polymerization of dienes, styrene, and acrylates. Oxidation gives *a,a,a′,a′*-tetramethylphenylenebiscarbinols. Dehydrogenation gives diisopropenylbenzenes, which by reaction with phenol or aniline give bisphenols or bisanilines, respectively, which are used as building blocks for polycarbonates, polyamides, polyesteramides, and polyurethanes (→Polyamides; →Polycarbonates; →Polyurethanes). Addition of isocyanic acid to diisopropenylbenzenes yields diisocyanates, from which light-stable polyurethanes can be produced [157]. Bis(*tert*-butylperoxyisopropyl)benzene, preferably prepared from the mixture of the corresponding biscarbinols of 1,3- and 1,4-DIPB, is used as a cross-linking agent for polyolefins.

3.9. Cymenes; C_4- and C_5-Alkylaromatic Compounds

The compounds listed in Table 17 are industrially important. Mixtures of 3-isopropyltoluene (*m*-cymene) and 4-isopropyltoluene (*p*-cymene) can be obtained by propylation of toluene in the presence of an isomerization-active Friedel – Crafts catalyst. These two isomers can be separated by distillation only with difficulty. The mixture is used for the production of *m*- and *p*-cresol, (→Cresols and Xylenols, Chap. 1.4.3.), [158]. Treatment of (methyl-)aromatic compounds with isobutene yields *tert*-butyl-substituted compounds, which are used as solvents (*tert*-butylbenzene) and for the production of fragrances, pharmaceuticals, and herbicides.

Table 17. Physical properties of some alkylbenzenes

Compound	CAS registry number	*mp*, °C	*bp*, °C	η_D^{20}
3-Isopropyltoluene	[*535-77-3*]	−63.75	175.05	1.4929
4-Isopropyltoluene	[*99-87-6*]	−67.94	177.10	1.4909
2-Isopropyltoluene	[*527-84-4*]	−71.54	178.15	1.5005
Isobutylbenzene	[*538-93-2*]	−51.48	172.76	1.4864
tert-Butylbenzene	[*98-06-6*]	−57.85	169.12	1.4926
4-*tert*-Butyltoluene	[*98-51-1*]	−53	192.7	1.4919
5-*tert*-Butyl-*m*-xylene	[*98-19-1*]	−18.3	209	1.4956
tert-Pentylbenzene	[*2049-95-8*]		192.38	1.4958

m-Cymene

p-Cymene

The introduction of a *tert*-pentyl group can be achieved by the use of *tert*-pentyl chloride as the alkylating agent and aluminum chloride, iron(III) chloride, or zirconium tetrachloride as the catalyst. 2-*tert*-pentylanthraquinone, obtained from *tert*-pentylbenzene and phthalic anhydride, is employed in the industrial production of hydrogen peroxide. Isobutylbenzene, required for the synthesis of pharmaceuticals and fragrances, is produced in industrial quantities by treatment of toluene with propene over catalysts containing alkali metals, such as potassium – graphite inclusion compounds or sodium – potassium on a support [159].

3.10. Monoalkylbenzenes with Alkyl Groups $>C_{10}$

Monoalkylbenzenes with secondary alkyl groups C_{10} to ca. C_{14} are used as starting materials for the production of alkylbenzenesulfonates (ABS) (→Surfactants). Only secondary alkylbenzenesulfonates with unbranched (linear) side chains (LABS) are of practical importance as raw materials for detergents, as they are extensively degraded (>90 %) by microorganisms in sewage plants after a relatively short period of time.

Before the introduction of LABS, which took place in the Federal Republic of Germany in 1962, alkylbenzenesulfonates with highly branched C_{12} side chains were used. These compounds, tetrapropylene benzenesulfonates, were produced from the products of alkylation of benzene with propene tetramer, itself obtained by the tetramerization of propene by contact with phosphoric acid. These sulfonates possess excellent detergent properties, but their biological degradeability is insufficient.

Production. Linear secondary alkylbenzenes are obtained industrially by reaction of benzene with secondary alkyl chlorides (chloroparaffins) or with olefins under the influence of a Friedel – Craft catalyst such as aluminum chloride, hydrofluoric acid, or sulfuric acid (→Acylation and Alkylation, Chap. 2.1., →Acylation and Alkylation, Chap. 2.1.1.). The following methods have been described for the production of the required alkyl chlorides and olefins [160]:

1) Dehydrogenation of $C_{10}-C_{13}$-*n*-alkanes, according to the Pacol process of UOP (see Section 2.1.2.1), on a fixed bed at 400 – 500 °C, with a conversion of 10 – 15 %; the ensuing mixture of internal olefins and unreacted alkanes is used for the alkylation of benzene. The *n*-$C_{10}-C_{13}$-alkanes used in the dehydrogenation are obtained from the kerosene fraction of crude oil by adsorption on molecular sieves, according to well known processes such as IsoSiv of Union Carbide, or Molex of UOP.
2) By chlorination of $C_{10}-C_{13}$-alkanes at ca. 100 °C to a conversion of ca. 30 %, and use of the resulting mixture of alkanes and secondary monochloroalkanes for alkylation of benzene.
3) By chlorination of $C_{10}-C_{13}$-*n*-paraffins as in 2) above, followed by dehydrochlorination (elimination of hydrogen chloride) of the monochloroalkanes at 200 – 300 °C over an iron catalyst to give linear alkenes with internal double bonds; these alkenes, in admixture with unreacted paraffins, are then used to alkylate benzene.
4) Metathesis of higher ($>C_{18}$) with lower ($<C_{10}$) internal olefins from the Shell SHOP process (see Section 2.1.2.2) to give olefins of intermediate molecular mass.

A $C_{10}-C_{13}$-α-olefin fraction suitable for use in detergents can also be obtained by thermal cleavage of $C_{20}-C_{40}$-*n*-paraffins at 500 – 600 °C, according to the older wax-cracking process of Shell (see Section 2.1.2.1).

The alkylation of benzene with chloroparaffin – paraffin mixtures takes place in the presence of aluminum chloride at ca. 50 °C. A relatively high proportion of 2-phenylalkanes is characteristic of secondary alkylbenzenes obtained in this manner [161, 162]. Dichloroalkanes, always present in the mixture of chloroparaffins even at low levels of chlorination, can lead to the formation of diphenylalkanes, 1,4-dialkyltetralins, and 1,3-dialkylindans. For formation and analytical detection see

Figure 8. Production of alkylbenzenes, process of Hüls AG [165]

[163]. The removal of these compounds from monoalkylbenzenes is difficult. Formation of these byproducts can be largely avoided by carrying out the alkylation of benzene with olefins from the dehydrochlorination, where dichloroalkanes are dehydrochlorinated to give tar-like products that are easily separated. In industrial production the reaction of $C_{10}-C_{13}$-olefins with benezene is carried out with a 1 : 10 molar ratio in the presence of anhydrous hydrofluoric acid at 10 °C, a process that dates back to 1949 [164]. The industrial process using the steps paraffin chlorination – dehydrochlorination – alkylation in the presence of hydrofluoric acid was first realized by Chemische Werk Hüls in 1962 [162]. This process is shown in Figure 8. In this way a quality standard for alkylbenzenes for use in detergents was created; in ecological terms, this standard is still valid.

3.11. Diphenylmethane

Diphenylmethane [*101-81-5*] benzylbenzene, $C_{13}H_{12}$, M_r 168.24, was first prepared in 1871 by Zincke from benzyl chloride and benzene in the presence of zinc dust or copper (I) oxide.

Physical Properties. Diphenylmethane forms colorless prismatic needles with a harsh herbaceous odor reminiscent of geranium leaves. It is insoluble in water, soluble in alcohol, ether, chloroform, and benzene.

mp	26 – 27 °C
bp	
101.3 kPa	261 – 262 °C
1.33 kPa	125.5 °C
d_4^{20}	1.006
Flash point ca.	130 °C
Enthalpy of formation (room temperature)	109.6 kJ/mol
Enthalpy of combustion (20 °C)	41.2×10^3 kJ/kg

Chemical Properties. As an araliphatic hydrocarbon, diphenylmethane displays the chemical properties of both aromatic and aliphatic compounds. It is difficult to limit substitution in the phenyl radicals to one of the rings; therefore, controlled syntheses of particular unsymmetrically substituted diphenylmethanes must be carried out by different paths. Under suitable reaction conditions the methylene group can also be substituted, e.g., by halogen or nitro groups. Benzophenone can be produced by oxidation, for example, with oxygen over various catalysts, chromic acid or dilute nitric acid. Hydrogenation in ethanol over a nickel catalyst leads to dicyclohexylmethane. When diphenylmethane is passed over platinum – charcoal at 300 °C, cyclization to fluorene takes place.

Production. Of the many known methods to synthesize diphenylmethane only a few are used commercially.

The Friedel – Craft reaction of benzyl chloride with benzene in the presence of aluminum chloride is an important method for production of diphenylmethane:

$$C_6H_5CH_2Cl + C_6H_6 \xrightarrow{AlCl_3} C_6H_5CH_2C_6H_5$$

Other known catalysts of this process are elemental aluminum, iron(III) chloride, antimony pentachloride, zinc chloride – hydrogen chloride and boron fluoride dihydrate. When sulfuric acid is used as a condensation agent diphenylmethane yields are 83 % [166] and with polyphosphoric acid yields are over 90 % [167].

Condensation of benzene with formaldehyde in presence of 85 % sulfuric acid yields 79 % diphenylmethane [168].

$$2\ C_6H_6 + HCHO \xrightarrow{H_2SO_4} C_6H_5CH_2C_6H_5$$

Quality Specifications. Commercial diphenylmethane should be at least 97 % pure (GC). It must be free of halogens and have a minimum melting point of 24 °C.

Uses. Diphenylmethane is used in the fragrance industry both as a fixative and in scenting soaps. It can serve as a synergist for pyrethrin in pesticides and insecticides [169, 170]. Diphenylmethane is recommended as a plasticizer to improve the dyeing properties [171], as a solvent for dyes [172], and as a dye carrier for printing with disperse dyes [173]. The addition of diphenylmethane to saturated, linear polyesters improves their thermal stability [174], and its addition to jet fuels increases their stability and lubricating properties [175].

Substituted diphenylmethanes are used as solvents for pressure-sensitive recording materials [176].

4. Biphenyls and Polyphenyls

In the series of aromatic hydrocarbons with polyphenyls or polyaryls of the general formula $C_6H_5(C_6H_4)_nC_6H_5$, only the lowest members ($n = 0$, 1) are economically important. Higher polyphenyls ($n > 2$) are also known and may be isolated from coal tar or from aryl halides by the Ullmann reaction.

4.1. Biphenyl

Biphenyl [*92-52-4*], phenylbenzene, diphenyl, $C_{12}H_{10}$, M_r154.2, was discovered in 1862 by Fittig by the reaction of bromobenzene with sodium metal. Berthelot obtained the compound in 1867 by passing benzene vapor through a heated tube. In 1875 Büchner demonstrated the presence of biphenyl in coal tar [177].

Physical Properties. Pure biphenyl is a white solid; when only slightly impure it has a yellow tint. It crystallizes from solution results as glossy plates or monoclinic prisms. Biphenyl is almost insoluble in water, but is easily soluble in organic solvents such as ethanol, diethyl ether, and benzene. The dipole moment and X-ray measurements demonstrate that the two benzene rings are coplanar in the solid state. In the melt, in solution, and in the vapor free rotation about the central C-C bond can take place; in substituted biphenyls, however, this rotation may be severely restricted, e.g., in dinitrodiphenic acid, leading to the existence of optically active isomers. The most important physical properties are listed below:

mp	69.2 °C [178]
bp (101.3 kPa)	255.2 °C [178]
d_4^{20} (solid)	1.041
d_4^{77} (liquid)	0.9896 [179]
n_D^{77}	1.5873
T_{crit}	515.7 °C [180]
p_{crit}	4.05 mPa
Flash point	113 °C [181]
Ignition temperature	570 °C
Heat of combustion	6243.2 kJ/mol
Heat of vaporization	53.9 kJ/mol
Heat of fusion	18.60 kJ/mol

The variation of some physical properties with temperature is given in Table 18 (see next page).

Table 18. Temperature dependence of some physical properties of biphenyl [179]

t, °C	100	200	300	350
Vapor pressure, kPa		25.43	246.77	558.06
Liquid density, g/cm^3	0.97	0.889	0.801	0.751
Heat capacity, J/g	1.786	2.129	2.468	2.640

Chemical Properties. Biphenyl is a very stable organic compound; in an inert atmosphere it remains unchanged even at a temperature >300 °C. The compound sublimes, distills with steam, and undergoes various substitution reactions; the reactivity is similar to, but less than that of benzene. Substitution reactions, e.g., chlorination, nitration, and sulfonation, occur at the 2- and 4-positions, the latter being the preferred site of attack in Friedel – Crafts reactions.

Production. *Hydrodealkylation of Benzene.* Biphenyl is currently obtained mainly as a byproduct in the production of benzene by thermal or catalytic hydrodealkylation of toluene (→Benzene, Chap. 5.3.1.) [182–185]. The reaction is carried out in a hot tube reactor at 700 °C with a hydrogen pressure of 4 MPa; the ratio of hydrogen to toluene is 4 : 1. Toluene conversion ranges from 35 to 85 %, with methane being formed at 2.5 mol % above the stoichiometric.

Biphenyl is obtained as the pot residue, following removal of gas and distillation of benzene and toluene; about 1 kg of biphenyl is obtained per 100 kg benzene. The biphenyl can be enriched to a purity of 93 – 97 % by distillation.

Thermal Dehydrocondensation of Benzene. Until the early 1970s, biphenyl was produced exclusively by specific thermal dehydrocondensation of benzene [186]. This process yields a higher quality product than the toluene route, e.g., distilled material with a purity >99.5 %; varying quantities of terphenyl isomers and several higher homologues are also obtained.

The slightly endothermic dehydrocondensation ($\Delta H = +8$ kJ/mol [187]) of benzene to biphenyl and terphenyl has been investigated intensively [188, 189]. The formation of biphenyl from benzene starts at ca. 480 °C and increases with increasing temperature and residence time.

Industrially, the reaction is carried out in a multitube reactor, heated electrically [190] or by heat exchanger, at 700 – 850 °C using residence times of the order of seconds. An optimal tube length of 45 – 75 m and diameter of 100 – 120 mm have been reported [191–194]. None of the published procedures work in equilibrium because carbon black formation increases with increasing temperature and longer residence time.

The preferred residence time is ca. 10 s, which results in a benzene conversion of ca. 10 % [192, 195]. By recycling the benzene, 1 kg of starting material may yield 0.8 – 0.85 kg biphenyl, 0.07 – 0.12 kg terphenyl, and some higher polyphenyls. The major technical problem in the production of biphenyl by dehydrocondensation of benzene is carbonization at the high temperature required [196]. The carbon deposit on the reactor tube walls and the release of large carbon flakes at bends or narrow passages within the tubes may lead to blockages. Countermeasures include addition of about 0.1 % oxygen or sulfur compounds, such as methanol, ethanol, acetone, or carbon disulfide [197–199] to the benzene feedstock, the use of special alloys [200, 201], uniform heating of the reactor by means of circulating gases, and high feedstock velocity, and the use of turbulent flow [192]. A proposal for further improving the process is to carry out the reaction in fluidized beds. Quartz sand [202] or sintered corundum [203] is used as energy carrier in this process; these materials are recycled after the carbon deposits have been removed by burning them outside of the reactor.

Other Synthetic Routes. In addition to these two industrial processes for the production of biphenyl, other synthetic routes have been described:

1) Ullmann reaction: heating halogenobenzenes with copper powder [204].
2) Pyrolysis of coal tar in the presence of molybdenum oxide – alumina catalyst [205, 206].
3) Reduction of phenyldiazonium chloride solution with copper and zinc [207].

4) Heating phenylmagnesium halides with copper(II) salts [208].
5) Oxidative dehydrocondensation of benzene [209–214]. Benzene is oxidized to biphenyl by platinum- or palladium salts in glacial acetic acid at 120 °C; the salts are reduced to the pure metals, and stoichiometric quantities of the salts are required.
6) Dehydrocondensation of benzene in the presence of catalytic quantities of noble metal salts requires reoxidation of the metals during the course of the reaction. This may be done with pure oxygen, but a partial pressure of 6 MPa is required [215]. Additives such as β-diketones [216], heteropolyacids [217], or organic copper salts [218] are incapable of significantly lowering the required oxygen pressure, so that a potentially explosive regime cannot be avoided [217]. Yields of biphenyl are ca. 260 mol %, calculated on the palladium salt charge.
7) Hydrodimerization of benzene to phenylcyclohexane, followed by dehydrogenation to biphenyl [219–223]:

Suitable catalysts for this dimerization are noble metals on molecular sieve, alkali metals on alumina or carbon, and transition metals such as nickel, tungsten, or zinc on the zeolites faujasite or mordenite. A selectivity of up to 87 % has been claimed. Subsequent dehydrogenation is carried out at about 400 °C over $Pt-Al_2O_3$ [223], $Cr_2O_3-Na_2O-Al_2O_3$ [222, 224], $Cr_2O_3-K_2CO_3-Fe_2O_3$ [225], or $Cr_2O_3-MgO-Al_2O_3$ [226] giving yields of up to 99 %. Data concerning residence times over the catalyst are not available, either for the hydrodimerization or the dehydrogenation processes.

Analysis. Gas chromatography is used to analyze biphenyl and its derivatives.

Storage and Transportation. Biphenyl is marketed as a solid in the form of plates, flakes, or pellets, containing <10 ppm benzene and with a biphenyl content of >99.5 %; it is transported in bags or fiber drums; in the molten state (ca. 120 °C) in tank cars. It is not a regulated material for transportation, on account of its toxicity; there are no restrictions for transportation by sea, land, or air. The greatest hazards in handling biphenyl are the risk of dust explosions and the ignition of biphenyl vapor – air mixtures over the molten product.

Uses. Biphenyl is an important heat transfer agent, because of its high thermal stability. It is used as a composite with diphenyl ether, especially as a melting point depressant. The eutectic mixture of 26.5 % biphenyl and 73.5 % diphenyl ether is marketed under the trade names Diphyl (Bayer), Dowtherm A (Dow), Thermic (ICI), Gilotherm (Rhône-Poulenc), Therm S 300 (Nippon Steel), Santotherm VP and Therminol VP-1 (both Monsanto) for use at up to 400 °C. The eutectic begins to boil at 256 °C; the vapor pressure at the maximum operating temperature (400 °C) is ca. 1.1 MPa.

A further large quantity of biphenyl is used as a dye carrier [227, 228]. Until a few years ago, polychlorinated biphenyls (PCBs), generated by chlorination of biphenyl, were produced in large quantities for use as nonflammable hydraulic fluids and as transformer dielectrics. Production has largely ceased on ecological considerations (→Chlorinated Hydrocarbons). Among the hydroxy derivatives, *o*- and *p*-hydroxybiphenyl and *p,p′*-dihydroxybiphenyl are used industrially. *o*-Hydroxybiphenyl is used as a preservative and fungicide. It is synthesized mainly from cyclohexanone (→Phenol Derivatives). *p*-Hydroxybiphenyl and *p,p′*-dihydroxybiphenyl are generated by sulfonation of biphenyl, followed by fusion with alkali.

Economic Aspects. According to a 1976 estimate, 67 % of the annual United States production of 40 000 t biphenyl was produced by dealkylation of toluene and 33 % by thermal dehydrocondensation of benzene [229].

The annual production for 1984 is estimated at 15 000 t, with an increasing proportion from dealkylation of toluene. The production capacities of the major producers, Monsanto, (United States), Bayer (Federal Republic of Germany), and Monsanto (United Kingdom) have not been

Table 19. Physical properties of terphenyls

disclosed. Based on the legal restrictions imposed on the use of PCBs, capacity should far exceed current demand.

4.2. Terphenyls

Physical Properties. The three isomeric terphenyls, $C_{18}H_{14}$, M_r230.29, are colorless to pale yellow crystalline solids [230–235]. Some physical properties are listed in Table 19.

o-Terphenyl
1,1′:2′, 1″-Terphenyl

m-Terphenyl

p-Terphenyl

Table 20. Terphenyl substitution pattern

	Position for substitution			
	First	Second	Third	Fourth
o-Terphenyl	4-	4″-	4′-	5′-
m-Terphenyl	4′-	4-	4″-	
p-Terphenyl	4-	4″-	2′-	

Chemical Properties. Terphenyls, like biphenyls, are thermally extremely stable organic compounds, again offering a potential for use as heat transfer media. Terphenyls are sublimable, steam volatile, and show the typical substitution reactions of aromatic hydrocarbons, such as bromination and nitration. The substitution pattern for the preferred positions of the three terphenyls is shown in Table 20.

Production. Terphenyls are byproducts in the production of biphenyl by dehydrocondensation of benzene; they are found in the high-boiling fraction of the pyrolysis products. The pot residue has the following approximate composition [240]:

3 – 8 %*o*-Terphenyl
44 %*m* – Terphenyl
24 %*p* – Terphenyl
1.5 %Triphenylene
22 – 27 %Higher polyphenylenes and tar.

When, in the early 1960s, terphenyl was proposed to be used as coolant and moderator in nuclear reactors [241], numerous reports were published of attempts to enhance the yield of terphenyl in dehydrocondensation reactions. Increasing the temperature or residence time was ruled out because of increased carbonization. These procedures also enhanced the biphenyl fraction, so that the latter had to be recycled to the reactor [193, 197, 242–244]. Recycling a concentration of up to 30 % biphenyl has been described [193]. A practical level appears to be using benzene with 10 % biphenyl [210]. Attempts have also been made to recycle the extremely high melting *p*-terphenyl, after isolation from the reaction mixture, to obtain a lower melting terphenyl mixture [242]. The *o*-derivative is readily separated from the terphenyl isomer mixture by distillation; *m*- and *p*-terphenyl distill together and the pure isomers can be ob-

tained by zone refining [245]. Terphenyl isomers, including hydrogenated terphenyl, can be analyzed by gas chromatography. The sole producer of terphenyl in the United States is Monsanto. The market amounts to several thousand tons per year. Terphenyl is available in Europe from Bayer.

Storage and Transportation. Solid terphenyl is shipped as flakes in laminated bags or in fiber drums, liquid, hydrogenated terphenyl in tank cars, steel drums, or barrels. Terphenyls and hydrogenated terphenyls possess a low toxicity, and are therefore not regarded as dangerous goods for the purpose of transportation.

Uses. Terphenyl is used as a heat transfer agent because of its excellent thermal stability; a mixture with a composition of 2 – 10 % *o*-terphenyl, 45 – 49 % *m*-terphenyl, 25 – 35 % *p*-terphenyl, and 2 – 18 % higher polyphenyls is used. This composition approximates the pot residue from the distillation of biphenyl. This mixture has *bp* ca. 360 °C; a disadvantage is the high *mp*, 145 °C. The largest fraction is partially hydrogenated to yield a clear oil, miscible with hydrocarbons and chlorinated hydrocarbons. Hydrogenation lowers the setting point and the viscosity but unfortunately also reduces the thermal stability. Partially hydrogenated terphenyl [246] is used mainly as a dye carrier for pressure sensitive recording materials and copy paper, and as a heat transfer oil. Heat transfer oils consisting of partially hydrogenated terphenyl isomers are marketed under the following trade names: Santotherm 66 or 88, Therminol (Monsanto, United States), Gilotherm (Rhône-Poulenc, France), and Therm S 900 (Nippon Steel, Japan). Their usage range extends to 340 °C.

4.3. Polyphenyls.

Polyphenyls with four or more phenyl residues have generally been synthesized as *p*-linked isomers and are used as scintillators [247]. They are economically unimportant.

A symmetrical hydrocarbon within this class is 1,3,5-triphenylbenzene, $C_{24}H_{18}$, *mp* 174 °C, prepared by condensation of three molecules of acetophenone.

5. Hydrocarbons from Coal Tar

Anthracene and Naphthalene and Hydronaphthalenes are separate keywords.

Hydrocarbons from coal tar are generally recovered in large-scale operations by distillation and crystallization, after the polar, co-boiling components, phenols and nitrogen bases, have been separated by extraction (→Tar and Pitch). Supplies of coal tar as a raw material have been sufficient to date to meet the demand for these hydrocarbons, so that no other production processes, such as syntheses, have yet been developed to the stage of commerciality. Hydrocarbons from coal tar are used predominantly in the synthesis of dyes, plastics, and pharmaceuticals.

5.1. Acenaphthene

Acenaphthene [*83-32-9*], $C_{12}H_{10}$, M_r 154.21, was discovered in coal tar in 1867 by BERTHELOT.

Physical Properties. Acenaphthene forms colorless needles; readily soluble in chloroform, toluene, and hot ethanol; soluble in cold ethanol, hot diethyl ether, and benzene; insoluble in water.

mp	95.4 °C
bp (101.3 kPa)	277.5 °C
ϱ (25 °C)	1.2195 g/cm^3
n_D^{100}	1.6048
T_{crit}	530 °C
Heat of fusion	1.344×10^5 J/kg
Heat of vaporization (40 °C)	3.48×10^5 J/kg
Heat of combustion (25 °C)	4.033×10^7 J/kg

Chemical Properties. Acenaphthene reacts with halogens, preferentially at 3-, 5-, and 6-positions, or at the 1-position when irradiated with visible light. Nitration and sulfonation occur at the 3-, 5-, or 6-positions. Catalytic hydrogenation leads to tetra- and decahydroacenaphthene. Decahydroacenaphthene can

be isomerized in the presence of Lewis acids to 1,3-dimethyladamantane. Oxidation of acenaphthene gives naphthalic acid or its anhydride, acenaphthenequinone, acenaphthenol, and acenaphthenone.

Production. High-temperature coal tar contains, on average, 0.3 % of acenaphthene; in addition, it is formed under the conditions of coal tar distillation by hydrogenation of acenaphthylene, which is found in crude tar at a level of 2 %. Acenaphthene is concentrated to ca. 25 % in the coal tar fraction boiling between 230 and 290 °C (wash oil), which is recovered at ca. 7 % in continuous tar distillation. The readily crystallizable acenaphthene fraction, boiling at 270 – 275 °C, is obtained from the wash oil by redistillation, or by removing it directly during primary tar distillation. From this, technical acenaphthene (95 – 99 % pure) is produced by crystallization in agitated coolers and centrifuges, or by continuous counter-current crystallization [256, 259]. The pure compound is obtained by further distillation and recrystallization.

Uses. Acenaphthene is used on a large-scale for synthesis of naphthalic anhydride by gas-phase with air oxidation at 300 – 400 °C, in the presence of vanadium containing catalysts [258, 259]. Liquid-phase oxidation with chromate or air in the presence of cobalt- or manganese acetate at 200 °C [260], or cobalt resinate at 120 °C [261] produces naphthalic acid (→Carboxylic Acids, Aromatic, Chap. 4.4.). Production of naphthalene-1,4,5,8-tetracarboxylic acid from acenaphthene by condensation with malonic acid dinitrile [262] is at present not industrially important. A technically feasible procedure has been developed using 5-methyl-*peri*-acenaphthindene-7-one [*42937-13-3*] (by reaction of acenaphthene with diketene in HF) (→Carboxylic Acids, Aromatic, Chap. 4.7.), [263]. Naphthalic anhydride and naphthalene-1,4,5,8-tetracarboxylic acid are used as intermediates for production of perylene and perinone pigments (→Pigments, Organic) [262]. Other valuable intermediates, particularly for the production of dyes and optical brighteners, and also for pharmaceuticals and pesticides, are produced from, e.g., 4-bromacenaphthene [264] (for 4-bromonaphthalic anhydride or naphthalic anhydride-4-sulfonic acid), from 5,6-dichloracenaphthene (for 4,5-dichloronaphthalic anhydride) [265] and from 3,5,6-trichloracenaphthene [266]. Nitration and oxidation of acenaphthene produce 4-nitronaphthalic anhydride, from which the fluorescent pigment Solvent Yellow 44 can be made [267]. Reaction of acenaphthalene with sodium cyanate in hydrofluoric acid gives acenaphthene-5,6-dicarboxylic acid imide, which can be used as an intermediate for dyes [268].

Bromination of acenaphthene in the presence of, e.g., iron(III)- or aluminum chloride, followed by further bromination by the addition of a radical initiator, such as azobisisobutyronitrile (AIBN), and subsequent dehydrobromination produces condensed bromacenaphthene, which is particularly well-suited for rendering plastics nonflammable and radiation-resistant [269]. Thermally stable plastics can be obtained from acenaphthene in the following ways: 1) by condensation with formaldehyde; 2) oxidation and reaction with an aromatic polyamine [270]; by cocondensation with phenol and formaldehyde [271]; and by condensation with terephthaloyl chloride [272]. Acenaphthene also serves as a feedstock for the production of acenaphthenequinone, acenaphthene, and dimethyladamantane [273].

Derivatives.

Acenaphthenequinone

Acenaphthylene

Acenaphthenequinone [*82-86-0*], $C_{12}H_6O_2$, M_r 182.17; *mp* 261 °C; yellow needles; slightly soluble in ethanol; soluble in hot benzene and toluene. It is formed by liquid-phase oxidation of acenaphthene with hydrogen peroxide or dichromate in acetic acid, by chlorination of dibromacenaphthylene followed by acid hydrolysis, or by condensation of acenaphthene with ethyl nitrite and separation of the dioxime. Acenaphthenequinone is suitable for use as an insecticide and fungicide and can be converted into vat dyes.

Acenaphthylene [*208-96-8*], $C_{12}H_8$, M_r 152.18; *mp* 92 – 93 °C; yellow prisms; soluble in ethanol, diethyl ether, and benzene; insoluble in water. It is found in coal tar at a concentra-

tion of 2 % and can be produced industrially by catalytic dehydrogenation of acenaphthene in the gas phase. Thermal, ionic, radical, or radiochemically induced polymerization produces polyacenaphthylene [274]. Polyacenaphthylene and copolymers with other olefins are characterized by high thermal and mechanical stability together with good electrical insulation properties. The thermal stability of polystyrene can be significantly increased by copolymerisation with acenapthylene [274]. Polymerisation of acenaphthylene with acetylene in the presence of a Lewis acid catalyst gives electrically conductive polymers; they are used for electronic engineering and for the antistatic finishing of plastics [275]. Thermosetting resins with good resistance to heat and chemicals can be obtained by cocondensation with phenol and formaldehyde [271]. Acenaphthylene possesses excellent properties as an antioxidant in cross-linked polyethylene and ethylene – propylene rubber [274]. Thermal trimerization of acenaphthylene leads to decacyclene, which can be further processed to sulfur dyes [276].

5.2. Indene

Indene [*95-13-6*], C_9H_8, M_r 116.16, was discovered in coal tar in 1890 by KRAEMER and SPILKER.

Physical Properties. Indene is a colorless liquid; insoluble in water; soluble in ethanol; it is miscible with diethyl ether, naphtha, pyridine, carbon tetrachloride, chloroform, and carbon disulfide.

mp	−1.5 °C
bp (101.3 kPa)	183 °C
ϱ (20 °C)	0.9966 g/cm^3
n_D^{20}	1.5763
Heat capacity (25 °C)	1.610×10^3 J/kg
Heat of fusion	8.33×10^4 J/kg
Heat of combustion (25 °C)	4.132×10^7 J/kg
Dipole moment (in CCl_4)	0.85 D

Chemical Properties. Indene polymerizes readily at ambient temperature and in the dark. Polymerization is accelerated by heat, acid, and Friedel – Crafts catalysts. Depending on reaction conditions, oxidation leads to dihydroxyindan, homophthalic acid, or phthalic acid. Hydrogenation produces indan. Halogenation occurs at the 2,3-double bond. Diene adducts are formed with maleic anhydride and hexachlorocyclopentadiene.

Production. Indene is found in high-temperature coal tar at an average concentration of 1 %. Pyrolysis residual oils from olefin production contain varying amounts of indene [277], which can be separated by extractive distillation with *N*-methyl-2-pyrrolidone [278] or by crystallization [279]. Indene is recovered industrially from dephenolated and debased tar light oil by rectifying distillation followed by crystallization. When the phenol extraction is omitted a highly concentrated indene fraction can also be obtained by azeotropic distillation of an indene – phenol fraction with water, whereby the phenol is separated as a bottom product [280].

Uses. Indene is used as a comonomer in coal-tar derived indene – coumarone and petroleum-derived aromatic hydrocarbon resins (→Resins, Synthetic). Technical pure indene is used for the production of indan and its derivatives. Esters of indene-1-carboxylic acid, which are effective as acaricides, can be synthesized from indene for use in, e.g., tick collars [281].

Derivatives.

Indan [*496-11-7*], hydrindene, C_9H_{10}, M_r 118.18;

mp	−51.4 °C
bp (1013 kPa)	176 °C
ϱ (20 °C)	0.9644 g/cm^3

Indan is a colorless liquid; insoluble in water; soluble in ethanol and diethyl ether. It is found at a concentration of 0.1 % in coal tar, but is mainly produced by catalytic hydrogenation of indene.

Alkylated indans are used in the production of synthetic lubricants (→Lubricants and Related Products). Indan is used for the synthesis of indanols (→Phenol Derivatives).

2-Indanol [*4254-29-9*], $C_9H_{10}O$, M_r 134.18; *mp* 69 °C; colorless crystals. It is obtained by hydrogenation of 2-indanone prepared by reaction of indene with hydrogen peroxide and boiling in sulfuric acid over a platinum catalyst in ethanol. 2-indanol is used in the synthesis of the coronary therapeutic, Aprindine [*37640-71-4*], *N*-(3-diethylaminopropyl)-*N*-indan-2-ylaniline; (→Antiarrhythmic Drugs), [282] and can be employed as an intermediate for other pharmaceuticals, e.g., for antihypertonics [283].

5-Indanol [*1470-94-6*], $C_9H_{10}O$, M_r 134.18; *mp* 55 °C; colorless crystals. It is produced by fusion of indan-5-sulfonic acid with potassium hydroxide [284]. 5-Indanol is used in the synthesis of the multi-purpose antibiotic, Carindacillin [*26605-69-6*] (6-[2-phenyl-2-(5-indanyloxycarbonyl)acetamido] penicillanic acid; →Antibiotics), [285]. 5-Indanylesters of substituted picolinic acids can be used as antihypertonic [286]. 5-Indanol itself may be used as an antidandruff additive in hair shampoos (→Hair Preparations) [287].

4-Indanol [*1641-41-4*], $C_9H_{10}O$, M_r 134.18; *mp* 49 – 50 °C; colorless crystals. Analogous to 5-indanol it is synthesized by potassium hydroxide fusion of indan-4-sulfonic acid, which is produced as a byproduct in indan sulfonation. Catalytic gas-phase amination of 4-indanol produces 4-aminoindan [288], which is required as an intermediate, e.g., for pharmaceuticals. Clorindanol (7-chloro-4-indanol) is used as an antiseptic.

5.3. Fluorene

Fluorene [*244-36-0*], $C_{13}H_{10}$, M_r166.22, was discovered in coal tar in 1867 by BERTHELOT.

Physical Properties. Fluorene forms colorless flakes with slight violet fluorescence; sublimes readily; insoluble in water; soluble in benzene, diethyl ether, carbon disulfide, and hot ethanol; soluble with difficulty in cold ethanol.

mp	115 °C
bp (101.3 kPa)	298 °C
ϱ (20 °C)	1.181 g/cm^3
Heat of fusion	1.21×10^5 J/kg
Heat of combustion (25 °C)	3.994×10^7 J/kg

Chemical Properties. Fluorene is capable of numerous chemical reactions, through both the aromatic rings and especially the reactive methylene group. Oxidation produces fluorenone. Reaction with dialkyl carbonate and alkali metal hydride or alcoholate, followed by neutralization and saponification of the resulting ester produces fluorene-9-carboxylic acid; the latter is also produced by metalation with butyl lithium followed by carboxylation. Nitration leads predominantly to 2-nitrofluorene, chloromethylation to 2-chlormethylfluorene. Halogenation, depending on the reaction conditions, gives the mono-, di-, or tri-haloderivatives, substitution taking place at the 2-, 2,7-, or 2,4,7-positions; in the presence of catalysts waxy products containing ca. 50 wt % chlorine are formed.

Production. High-temperature coal tar contains on average, 2 % fluorene. The latter is recovered industrially by redistillation of coal tar wash oil or by direct removal of a fluorene fraction during primary distillation of coal tar, followed by recrystallization of the fluorene fraction (dephenolated and debased if necessary) e.g., from solvent naphtha or naphtha [289]. Fluorene can be isolated from a ≥60 % fluorene fraction by continuous counter-current crystallization [290]. It is possible to refine the technical product further via the sodium compound (by reaction with sodium or sodium amide), or by sulfuric acid purification and crystallization from methanol.

Uses. Fluorene is the starting material for production of fluorenone and fluorene-9-carboxylic acid. Fluorene-9-carboxylic acid is an intermediate in the production of antidiabetic and antiarrhythmic drugs, and plant growth regulators [291]. Plant growth regulators are also obtained by reaction of fluorene with phthalic anhydride [292]. Fluorene-2-acetic acid (by acylation of fluorene) can be used as a precursor in

the synthesis of anti-inflammatory drugs [293]. Reaction of fluorene with sulfur produces electrically conductive polymers [294]. The azine dye Sirius Light Violet FRL is produced from 2-aminofluorene (→Azine Dyes, Chap. 5.2.). The fluorene analog of malachite green dye is obtainable from 3,6-bis-(dimethylaminofluorene) [295]. 2,7-Diiodofluorene can be employed in the production of styryl dyes for optical brighteners [296]; heptabromofluorene can be used as a fire-retardant for plastics [297]. Fluorene itself can be used in admixture with biphenyl and phenyltoluene as a carrier for dyeing polyester fibers [298].

Derivatives.

9-Fluorenone [*486-25-9*], $C_{13}H_8O$, M_r 180.21;

mp	85 – 86 °C
bp 101.3 kPa)	341.5 °C
ϱ (99.4 °C)	1.130 g/cm^3
n_D (99.4 °C)	1.6369

9-Fluorenone forms yellow crystals; insoluble in water; soluble in hot sulfuric acid; very readily soluble in ethanol and diethylether; volatile in steam. Fluorenone can be produced by catalytic oxidation of fluorene [261, 299–302], or of fluorene fractions in the presence of a quaternary ammonium salt [303], or by catalytic oxidative cracking (oxicracking) of suitable aromatic [304].

Di- and trinitrofluorenones are synthesized from fluorenone for use as electron acceptors in electrophotography, e.g., in copying systems [305]. 2,4,7-Trinitrofluorenone is used as an analytical reagent for polynuclear aromatic hydrocarbons. Fluorenone can be used as starting material for the synthesis of imidazolylfluorene salts with antimycotic activity [306]. 9,9-Bis(4-hydroxylphenyl)fluorene (from fluorenone by reaction with phenol [307]) can be used as starting material for thermally stable plastics [308]. 9,9-Bis(4-methylaminophenyl)fluorene (from fluorenone by reaction with phenyl methyl amine) has been suggested as a hardener for epoxy resins [309]. Fluorenone is also suitable as an oxidizing agent in the Oppenauer reaction.

5.4. Fluoranthene

Fluoranthene [*206-44-0*], $C_{16}H_{10}$, M_r 206.26, was isolated from coal tar by Fittig and Gebhardt in 1878.

Physical Properties. Colorless crystals with light blue fluorescence; insoluble in water; readily soluble in diethyl ether, boiling ethanol, chloroform, carbon disulfide, and glacial acetic acid.

mp	110 °C
bp (101.3 kPa)	384 °C
ϱ (20 °C)	1.236 g/cm^3
Heat of vaporization	3.29×10^5 J/kg
Heat of combustion (25 °C)	3.913×10^7 J/kg

Chemical Properties. Oxidation of fluoranthene with chromic acid leads to fluorenone-1-carboxylic acid via fluoranthene-2,3-quinone; hydrogenation leads to 1,2,3,10 b-tetrahydrofluoranthene, and to perhydrofluoranthene via decahydrofluoranthene. 2,3-Dihydrofluoranthene is obtained by metalation with sodium. Halogenation, nitration, and sulfonation take place predominantly at the 4-position. Condensation with phthalic anhydride in the presence of aluminum chloride gives a mixture of 7,8- and 8,9-phthaloyl fluoranthene.

Production. Fluoranthene belongs to the main constituents of high-temperature coal tar, which contains, on average, 3.3 % of fluoranthene. It is recovered from the fluoranthene fraction, which boils at 373 – 385 °C, and is obtained from the high-boiling anthracene oil II and from pitch distillate by redistillation. Subsequent recrystallization of the fluoranthene fraction from

solvent naphtha gives 95 % pure fluoranthene. Further refining is carried out by recrystallization from xylene with simultaneous partial sulfonation of the impurities with ca. 1 % of concentrated sulfuric acid, or by recrystallization from a pyridine – water mixture.

Uses. Fluoranthene is used in the production of fluorescent dyes (→Fluorescent Dyes). Yellow vat dyes are obtained by condensation with phthalic anhydride, via phthaloyl fluoranthenes, whereas bromination [310] and condensation with 1-amino-4-benzoyl-amino anthraquinone produces olive dyes [311]. 2-Benzylfluoranthene (from 2,3-dihydrofluoranthene [312] and benzaldehyde) can also be used for the production of dye intermediates [313]. Fluoranthene and alkyl fluoranthenes can be used as stabilizers in epoxy resin adhesives [314], as additives in electrically-insulating epoxy resin compositions [315], and in electrically-insulating oils [316]. 2,3-Dihydrofluoranthene and 1,2,3,10 b-tetrahydrofluoranthene [317] are used for numerous derivatives, some of which (e.g., their derivatives of phenylethyl amine) are of pharmaceutical interest. 7-Fluoranthenyl aminoalcohols (for cytostatics, anthelmintics, or bactericides [318]) and bis-aminoketones, e.g., 3,8-bis(4-piperidinobutyryl)fluoranthene (as antiviral agents [319]) can be synthesized from fluoranthene.

5.5. Phenanthrene

Phenanthrene [*85-01-8*], $C_{14}H_{10}$, M_r178.24 was discovered in coal tar by FITTIG and OSTERMAYER in 1872.

Physical Properties. Colorless flakes with weak blue-violet fluorescence; readily sublimable; insoluble in water; slightly soluble in ethanol; readily soluble in diethyl ether, benzene, carbon disulfide, and glacial acetic acid.

mp	101 °C
bp (101.3 kPa)	338.5 °C
ϱ (20 °C)	1.172 g/cm^3
Heat capacity (25 °C)	1.361×10^3 J/kg
Heat of fusion	1.04×10^5 J/kg
Heat of combustion (25 °C)	3.982×10^7 J/kg

Chemical Properties. Phenanthrene can be oxidized to phenanthrenequinone, diphenic acid, or to phthalic acid, depending on the oxidant. Hydrogenation produces 9,10-di-, tetra-, octa-, or perhydrophenanthrene. Phenanthrene is halogenated predominantly in the 9,10-positions, and nitrated in the 9-position. Sulfonation leads to mixtures of 2-, 3-, and 9-phenanthrene sulfonic acids. For acylation see →Acylation and Alkylation, Chap. 2.2.2.

Production. Phenanthrene, at a concentration of 5 %, is the second most important coal tar constituent in terms of quantity after naphthalene. During primary distillation of coal tar, it is concentrated in the anthracene oil fraction. After crystallization of the anthracene residues the phenanthrene is recovered as a fraction from the filtrate of this crystallization, or from the top fraction of crude anthracene distillation, by redistillation. Technically pure grades of phenanthrene are obtained by sulfuric acid refining and recrystallization from methanol, or by repeated rectification of the phenanthrene fraction. The accompanying substances can be separated either by partial sulfonation, or by partial condensation with formaldehyde and hydrogen chloride. The most persistent accompanying substance, diphenylene sulfide, can be completely removed by treating the melt with sodium and maleic anhydride.

Uses. Phenanthrene forms the basis for production of 9,10-phenanthrenequinone and 2,2′-diphenic acid (see Chap. 4) [320]. It can be used to synthesize anthracene, via the isomerization product of *sym*-octahydrophenanthrene (→Anthracene). Electrically conductive substances, e.g., for use in batteries and solar cells, can be produced by the electrochemical conversion of phenanthrene diazonium salts in a solvent containing a conductive salt, and subsequent doping with various ions (e.g., Na^+, Ba^{2+}, H^+, etc.) [321]. Liquid-crystalline 7-*n*-alkyl-9,10-dihydrophenanthrene-2-carboxylic acid ester, used for optical-electronic ap-

plications, can be synthesized from 9,10-dihydrophenanthrene [322]. By cross-linking with *p*-xylylene glycol and 4-toluenesulfonic acid, polycondensed thermosetting resins are obtained for composites or temperature-resistant, electrically insulating coatings [323]. A polyamide – polyimide resin can be produced by oxidation of phenanthrene to phenanthrene-9,10-quinone and -9,10-diol, condensation with formaldehyde, oxidation to the polycarboxylic acid, formation of the anhydride and finally reaction with an aromatic diamine. This resin is suitable for use in high-temperature insulators, printed circuit boards, and laminates [324]. Phenanthrene has been proposed as a plasticizer for plastics and molding compounds [325], phenanthrene and alkylphenanthrenes have been suggested as stabilizers for mineral oil products [326,327]. Deep khaki vat dyes are prepared by heating a mixture of phenanthrene and anthracene with sulfur [328]. [(Phenanthrylmethyl)amino]-propandiol, which possesses antitumor activity, can be synthesized via phenanthrene-9-carboxaldehyde [329].

Derivatives.

Phenanthrene-9-10-quinone [*84-11-7*], $C_{14}H_8O_2$, M_r 208.91; *mp* 217 °C; orange needles; poorly soluble in water; slightly soluble in ethanol; soluble in boiling water and in diethyl ether; readily soluble in hot glacial acetic acid. Phenanthrene-9,10-quinone is produced by liquid-phase oxidation of phenanthrene with chromates [330], catalytically with oxygen [331], with *tert*-butylhydroperoxide [332,333] or via phenanthrene-9,10-oxide with nitric acid or hypochlorite [334,335]. Further oxidation transforms the quinone into 9-hydroxyfluorene-9-carboxylic acid, which is used in the form of its salts or esters (in combination with the herbicide methyl chlorophenoxyacetic acid (MCPA), trade name: Aniten) or as the 2-chloro derivative (trade name: Maintain) as plant growth regulators [336,337]. Phenanthrene-9,10-quinone has been suggested as an additive for photographic or electrophotographic applications [308,338, 339], in UV-curable coatings and adhesives [340,341] and in production of cellulose by wood pulping [342]. An intermediate for azo pigments can be obtained by condensation with hydrazinobenzoic acid [343]. Condensation with aromatic amines gives intermediates for pharmaceuticals (e.g., immuno-suppressives) or fungicides [344,345].

5.6. Pyrene

Pyrene [*129-00-0*], $C_{16}H_{10}$, M_r202.26, was found in coal tar by Graebe in 1871.

Physical Properties. Colorless crystals with blue fluorescence; insoluble in water; very readily soluble in diethyl ether, benzene, and carbon disulfide; poorly soluble in ethanol.

mp	150 °C
bp (101.3 kPa)	393.5 °C
ϱ (23 °C)	1.271 g/cm^3
Heat capacity (18 °C)	1.126×10^7 J/kg
Heat of vaporization	3.21×10^5 J/kg
Heat of combustion (25 °C)	3.878×10^7 J/kg
Dielectric constant (17 °C)	3.21

Chemical Properties. Pyrene is oxidized by mild oxidants such as chromic acid to pyrene-1,6- and 1,8-quinone; further oxidation leads to perinaphthenone [*548-39-0*] and napthalene-1,4,5,8-tetracarboxylic acid. Hydrogenation produces, depending on the reaction conditions, ditetra-, hexa- or decahydropyrenes; halogenation products substituted in the 1-, 1,6-, 1,8-, 1,3,6- and 1,3,6,8-positions. The substitution pattern for halogenation can be changed in favor of the 4-position by Diels – Alder reaction with hexachlorocyclopentadiene [*77-47-4*] in the presence of iron powder or thallium acetate, followed by retro-Diels – Alder reaction. With nitration and sulfonation the 1-, 1,6-, and 1,3,6,8-substitution products are formed. Pyrene can be condensed with phthalic anhydride by Friedel – Crafts reaction to give diphthaloyl pyrenes, and with benzoyl chloride to the dye pyranthrone [*128-70-1*].

Production. High-temperature coal tar contains an average of ca. 2 % of pyrene. It is recovered from a fraction crystallizing above 110 °C, which is obtained by redistillation of the high-boiling anthracene oil II or pitch distillate. Pure pyrene is produced by recrystallization, e.g., from solvent naphtha [346] or by fractional crystallization from the melt [256], dephenolation and debasing, and by refining with 80 % sulfuric acid. As an alternative to sulfuric acid refining, the pyrene-accompanying brasane (2,3-benzodiphenylene oxide) can also be separated by recrystallization from xylene by adding iron(III) chloride. Traces of tetracene are removed by reaction with maleic anhydride.

Uses. The dye intermediate naphthalene-1,4,5,8-tetracarboxylic acid [*128-97-2*] can be produced by halogenation of pyrene [347, 348] (halogenation of the pyrene fraction is also possible [349]) followed by oxidation (→Carboxylic Acids, Aromatic, Chap. 4.7.), [350]. Other pyrene-based dyes are Sirius Light Blue F 3 GL from 3-aminopyrene (→Azine Dyes, Chap. 5.2.) and the green fluorescent dye, pyranin (Solvent Green 7), from pyrene-1,3,6,8-sulfonic acid [351]. Anthraquinone dyes (e.g., pyranthrone) may be obtained from dibenzoyl pyrene or diphthaloyl pyrene. Optical brighteners may be synthesized by reaction of pyrene with a complex of cyanuric chloride and aluminum chloride (→Optical Brighteners) [352]. By analogy to fluoranthene, pyrene and alkylpyrenes can be used as additives in electro-insulating oils [316], and in epoxy resins for electrical-insulation [315]. In a similar manner to phenanthrene, thermosetting resins may be formed with *p*-xylene glycol and 4-toluenesulfonic acid [323]. Condensation products of 1-bromopyrene or nitropyrene with formaldehyde are used as photoconductive substances in electrophotography [305, 353, 354]. 1,2,3,6,7,8-Hexahydropyrene is effective as a synergist for dialkylsulfide antioxidants in lubricants [355]. On the basis of pyrene, pyrenyl aminoalcohols can be synthesized as cytostatics, anthelmintics, or bactericides [356]. Pyrene itself can serve as an electron donor to increase the blackness in pencil leads [357].

6. Toxicology and Occupational Health

6.1. Alkanes

Methane is toxicologically virtually inert. In very high concentrations (80 – 90 vol %) it causes respiratory arrest [358]. The bulk of an inhaled dose is exhaled unchanged [359].

Ethane easily causes dyspnea in laboratory animals, beginning at concentrations of approximately 2 – 5 vol % in the air inhaled [360]. At high concentration respiratory arrest occurs [361]. A slight sensitization of the myocard to catecholamines has been described at a concentration of 15 – 19 vol % [362].

Propane has narcotic properties [361]. It is neither a skin nor a mucosal irritant. At very high concentration it also causes respiratory arrest [363]. In dogs adverse effects on circulatory function were found with inspiratory concentrations of 1 % or greater. A negative inotropic effect, a drop in the mean aortic pressure, and an increase in pulmonary vascular resistance were found [364].

MAK (1987): 1000 ppm.

Butane causes slight drowsiness beginning at a concentration of 10 000 ppm in the air inhaled [365]. In the mouse the inhalatory LC_{50} is 680 g/m^3 [366]. It has been proven in the dog that butane also sensitizes the myocardium to the effects of catecholamines [364].

MAK (1987): 1000 ppm.

n-*Pentane* has a less pronounced narcotic effect than the C_1–C_4 hydrocarbons. In humans the lowest lethal dose after acute inhalatory exposure is apparently 130 000 ppm, the lowest toxic dose 90 000 ppm [367]. Pentane apparently possesses a neurotoxic effect, although it is not very pronounced [368, 369].

n-*Hexane* possesses a marked neurotoxic effect that distinguishes it from the other alkanes. The causal factor for peripheral neuropathies is the oxidation product (cytochrome P 450-dependent oxidases) 2,5-hexadione. Toxicity manifests itself clinically in polyneuropathies [370, 371]. Hexane is also a skin irritant. The LC_{50} (inhalation mice) is 120 g/m^3 [372]. In rats the acute oral LD_{50} is 24 – 49 mL/kg [373]. Hexane is absorbed through the skin. Dermal exposure can lead to poisoning (LD dermal in rabbits ca. 5 mL/kg) [374]. In rats subchronic expo-

sure to a concentration of 400 – 600 ppm leads to neuropathies [375], which are characterized by degeneration of both myelin sheaths and axons [376–378].

MAK (1987): 50 ppm.

n-*Heptane* has narcotic properties. In humans 0.1 % in the inhaled air leads to dizziness and 0.5 % to equilibrial disturbances with loss of motor coordination [365]. Within 3 min 4.8 vol % in the air inhaled leads to asphyxia [379]. Like hexane, heptane is a skin and mucosal irritant [365]. The biotransformation of *n*-heptane, as with hexane, is by oxidation. Heptane apparently also possesses neurotoxic properties [380]. Myocardial sensitization to catecholamines has also been found [381].

MAK (1987): 500 ppm.

n-*Octane* is similar to *n*-heptane in regard to its narcotic effect; however, it does not seem to cause any other effects on the nervous system [372]. Octane is also metabolized by oxidation [382].

MAK (1987): 500 ppm

Only limited toxicological data are available on the higher molecular mass alkanes.

6.2. Alkenes

The alkenes under consideration are toxicologically not very active. Higher molecular mass compounds possess narcotic properties. The alkenes are not neurotoxic. The α-olefins generally seem to be more reactive and toxic than the β-isomers.

6.3. Alkylbenzenes

Trimethylbenzenes. The toxicological data available on trimethylbenzenes is mainly rather old. The acute inhalatory toxic dose for the 1,2,4- and the 1,3,5-isomers is in the range 7000 – 9000 ppm [383, 384].

As a result of their occurrence in automotive fuel and heating oil, low concentrations of trimethylbenzenes can be demonstrated in air and water. For example, measurements in 1974 in a tunnel in Rotterdam indicated a level of 0.015 ppm pseudocumene; see [385] for more details. An analysis of the drinking water of Cincinnati, Ohio, in 1980, revealed a concentration of 45 ng/L hemimellitene, 127 ng/L pseudocumene, and 36 ng/L mesitylene [386]. Trimethylbenzenes are toxic to aquatic organisms; LC_{50} values between 10 and 100 ppm have been reported [387].

The TLV (TWA) level for trimethylbenzene is 25 ppm [388]. The MAK for Trimethylbenzenes (all isomers (1,2,3–;1,2,4–;1,3,5–) has been set at 20 ppm. [389]. The United States toxicity assigment ranges from low to moderately toxic for pseudocumene, to highly toxic for the isomer mixture; disturbances in the central nervous system and abnormal blood pictures have been reported [387].

Tetramethylbenzenes. The oral toxicity of tetramethylbenzenes is low; LD_{50} >5000 mg/kg (rat, oral). Durene is additionally classified as intravenously highly toxic; LD_{50} 180 mg/kg (i.v., mice). Tetramethylbenzenes cause mild skin reactions [387]. Two values are cited for the odor threshold concentration of durene: 0.083 and 0.087 mg/m^3 [385].

Hexamethylbenzene. Hexamethylbenzene has low oral toxicity; LDLo 5000 mg/kg (rat). It is, however, suspected of causing neoplastic effects. Addition of nitromethane to hexamethylbenzene can lead to an explosive reaction [387].

Diethylbenzenes. Diethylbenzene is more toxic than monoethylbenzene (→Ethylbenzene) [390]. DEB is emitted into the environment from engine fuel and heating oil [386]. Diethylbenzenes are toxic to aquatic organisms; the LC_{50} is between 10 and 100 mg/L [387]. In the cell multiplication inhibition test with protozoa, the toxicity threshold is <10 mg/L [385]. In the Federal Republic of Germany DEB is classified as an aquatic hazard; aquatic hazard class 2. DEB causes mild to moderate irritation of the eye and mucous membranes. The oral toxicity is low: LDLo 5000 mg/kg (rat) [387]. The vapor possesses an anesthetic action and may cause headache, vertigo, or vomiting; the odor threshold concentration is <10 ppm [391].

Triethylbenzene. The LC_{50} of triethylbenzene (aquatic organisms) is between 100 and 1000 mg/L. The oral toxicity is low: LDLo 5000 mg/kg (rat). Implant experiments with hexaethylbenzene in mice have raised the suspicion that the compound may be carcinogenic [387].

Ethyltoluene. Ethyltoluene can, as with aromatic hydrocarbons, be detected in the environment [385]. The oral toxicity of 2- and 4-ethyltoluene is low: LDLo 5000 mg/kg (rat) [387].

Cumene. Cumene appears to be orally as nontoxic as propylbenzene, it is even less so by inhalation [383,392,393]. Cumene has a prolonged depressant effect on the central nervous system [394].

The MAK for cumene has been set at 250 mg/m^3, corresponding to a cumene vapor concentration in air of 50 mL/m^3. The vapor pressure of cumene at 20 °C is 0.5 kPa. There is a risk of cumene being absorbed through the skin [395]. Inhalation of cumene vapor leads to the delayed appearance of a long lasting narcotic effect [396].

6.4. Biphenyls and Polyphenyls

Biphenyls. Biphenyl dust or vapor is irritating to the eye and mucous membrane at a concentration as low as 3 – 4 ppm [390], and to the skin after extended exposure. A concentration of >5 mg/m^3 for long periods is considered a health hazard; systemic toxic effects were elicited in humans by a concentration with inhalatory exposure maxima of 128 ppm [400,401]. The olfactory threshold is ca. 0.06 – 0.3 mg/m^3. Some toxicity data are listed below [397–399]:

LD_{50} (rat, oral)	3280 mg/kg
LD_{50} (rabbit, oral)	2400 mg/kg
LD_{50} (rabbit, dermal)	2500 mg/kg
TL_m (fathead minnow, 96 h)	1.5 mg/L

Triphenyls are only minimally toxic [402].

Terphenyls. Toxicologically, terphenyl isomers should be treated like biphenyl. The oral LD_{50} is ca. 4.6 – 4.7 g/kg [403]. The toxicity of partially (40 %) hydrogenated terphenyl (LD_{50} 17.5 g/kg) is much less than that of the fully aromatic terphenyls [404–407].

6.5. Hydrocarbons from Coal Tar

The aromatic hydrocarbons under consideration are usually found in complex mixtures of various other polycyclic aromatic hydrocarbons (PAH), which originate from combustion emissions and industrial processes. For this reason toxic phenomena possibly caused by exposure to humans are often unlikely to be attributed to one single aromatic compound. Incorporation of these compounds into the body occurs predominantly by way of the respiratory tract. Skin contact is important with occupational exposure.

6.5.1. Biological Effects

6.5.1.1. Carcinogenicity and Mutagenicity

The aromatic compounds under discussion are considered as noncarcinogens, but pyrene and fluoranthene are able to enhance the carcinogenic potential of benzo [*a*] pyrene [*50-32-8*] when applied simultaneously to mouse skin (cocarcinogenic effect) (→Carcinogenic Agents) [408]. Phenanthrene resulted in just one positive tumor-initiation test in a series of carcinogenicity studies [408,409]. Acenaphthene, known as an inhibitor of mitosis in plant cells [410], induced the initial phase of bronchocarcinoma in rats after an inhalation period (4 months) of 4 hours per day with 0.5 – 1.25 mg/m^3 [411], but was negative in repeated topical application to mouse skin [412]. With their low activity in in vivo and in vitro assays, there is limited evidence that phenanthrene and pyrene are mutagenic [408,409,413–415]. As for fluoranthene, several more recent positive results indicate a mutagenic potential [408,416–419].

So far, tests on fluorene have given negative results [408].

6.5.1.2. Mammalian Toxicity and Toxicokinetics

The acute toxicity of the aromatic compounds under consideration is low: LD_{50} (oral and dermal) is 700 – 2700 mg/kg body weight in rodents [408,409,411,413]; LD_{50} (rat, oral) for acenaphthene is 10 000 mg/kg [421]. The LC_{50} (inhalation) of pyrene is reported to be 170 mg/m^3 [413]. No fatalities occurred in rats exposed to indene vapor (800 – 900 ppm) for six inhalation periods of 7.5 h each; however, systemic pathological changes in the vascular system and several organs were observed [412].

Longterm inhalation (4 months) of acenaphthene (0.5 – 1.25 mg/m^3) [411,420] or pyrene (0.3 – 3.6 mg/m^3) [408,409,413] caused local irritation and systemic pathological effects in several organs and the blood of rodents. In direct contact at high concentration, the compounds under consideration are irritating to the skin and mucous membranes; the tri- and polycyclic aromatics especially are photosensitizing [408–410,412,413]. The compounds under consideration are absorbed on inhalation or oral exposure, and partly leave the body unchanged in the feces and by exhalation [408,409,412,413]. After metabolic conversion to more water-soluble intermediates (hydroxylation and conjugation), they are excreted into the bile or the urine. The half-life of pyrene is estimated to be 24 – 48 h in rats and swine [413].

6.5.1.3. Ecotoxicology

Several studies have shown that the aromatic compounds, in question are microbially decomposed [422–424], although the microbial conversion of indene has not yet been described. These compounds tend to be enriched in sediments, sludges, and aquatic organisms because of their low water solubility. As a result of microbial degradation, biotransformation, and photochemical decomposition, however, accumulation is limited and checked. Nonetheless, a concentration in water of the order of their low solubility (<0.2 – 4.0 mg/L) may have adverse effects on aquatic life, as shown for acenaphthene [425], phenanthrene, and pyrene [426,427].

6.5.2. Safety Regulations

A threshold limit value (TLV) at the work place exists only for indene: 10 ppm (45 mg/m^3) (ACGIH, United States 1980). No other TLVs have so far been established. The United States standard for exposure to coal tar volatiles (0.2 mg/m^3) was recommended to be used in case of pyrene-containing PAH mixtures, but a maximum level of 0.1 mg/m^3 should be applied in the case of exposure to pure pyrene [413]. With the exception of indene all aromatics are included in the recommended United States list of priority pollutants (United States EPA, 1977) [428].

1. Introduction

Hydrochloric acid, also known as muriatic acid, is a solution of hydrogen chloride (HCl) [*7647-01-0*] in water. Both hydrochloric acid and hydrogen chloride are discussed in this article.

History. In the 15th century, the German alchemist VALENTIN heated so-called green vitriol [iron (II) sulfate, $FeSO_4 \cdot 7\,H_2O$] with common salt. He thereby obtained what then was called spirit of salt. In the 17th century, GLAUBER prepared hydrochloric acid from common salt and sulfuric acid. In 1790, DAVY established the composition of hydrogen chloride by synthesizing it from hydrogen and chlorine. In the same year, LEBLANC discovered the process named after him for the production of soda, the first stage of which is to react common salt with sulfuric acid, liberating hydrogen chloride. This was at first considered an undesirable byproduct and simply released into the atmosphere in large amounts. In 1863, English soda producers were compelled by the Alkali Act to absorb the hydrogen chloride in water, which quickly led to large-scale industrial use of the acid produced. Excess hydrogen chloride that could not be used as hydrochloric acid was oxidized to chlorine.

The industrial synthesis of hydrogen chloride followed the development of the chlor-alkali electrolytic process early in the 20th century. This route was used in addition to that based on the reaction between chlorides and sulfuric acid or sodium hydrogen sulfate and resulted in a product of higher purity.

These processes are becoming less important because of the large amounts of hydrogen chloride arising as byproducts of chlorination processes such as the production of vinyl chloride from ethylene. Hydrochloric acid may also be recovered from gases produced by the incineration of chlorine-containing waste, a consequence of the ever-increasing emphasis on environmental protection.

2. Properties

2.1. Physical Properties

Under standard conditions, hydrogen chloride, HCl, M_r 36.461, is a colorless gas with a pungent odor and an extremely mordant effect on the mucous membranes of the respiratory system. Some physical properties of hydrogen chloride are given below.

Figure 1. Density ϱ of liquid hydrogen chloride

Solid hydrogen chloride undergoes a polymorphic transition at 98 K from an orthorhombic face-centered low-temperature phase II to a cubic face-centered high-temperature phase I: enthalpy of transformation $\Delta H = 1190$ J/mol, entropy of transformation $\Delta S = 12.1$ J mol^{-1} K^{-1} [3]. The vapor pressure of solid hydrogen chloride, in millibars, is given [1] by

$$\log p = -911.31T^{-1} + 7.1875 + 4.313 \times 10^{-3}T$$

On melting the volume increases by 14 %.

The density, specific heat, viscosity and surface tension, thermal conductivity, and enthalpy of vaporization of *liquid hydrogen chloride*, each as a function of temperature, are shown in Figures 1, 2, 3, 4, 5, respectively. The vapor pressure of liquid hydrogen chloride, in millibars, is given by

$$\log p = -8.555 \times 10^2 T^{-1} + 7.553$$

which is fairly accurate over the entire liquid range.

∗ Hydrogen chloride forms addition compounds with many organic compounds; in such cases, its solubility often either is unknown or cannot be defined exactly.

The vapor density of *gaseous hydrogen chloride* shows that it consists of single HCl molecules. The specific heat, viscosity, and thermal conductivity of *gaseous hydrogen chloride,* each as a function of temperature, are shown in Figures 678, respectively [4]. The solubility of hydrogen chloride in various organic solvents is listed in Table 1 [5–7].

Figure 6. Specific heat c_p of gaseous hydrogen chloride

Figure 7. Viscosity η of gaseous hydrogen chloride at 101.3 kPa

Figure 8. Thermal conductivity λ of gaseous hydrogen chloride at 101.3 kPa

The most important thermodynamic data are as follows [8]:

Enthalpy of formation	
ΔH_f^0 (298.15 K)	−92.31 kJ/mol
Entropy S^0 (298.15 K)	186.78 J K^{-1} mol^{-1}
Enthalpy H^0 (298.15 K) − H^0 (0)	8.64 kJ/mol
Specific heat c_p (298.15 K)	29.12 J mol^{-1} K^{-1}
Free energy of formation	
ΔG^0 (293.15 K)	−95.25 kJ/mol

Figure 9. Heats of solution (25 °C) in the HCl–H_2O system a) Total enthalpy of solution $\Delta_{sol} H_{HCl}$, in kilojoules per gram of hydrogen chloride; b) Total enthalpy of solution in kilojoules per gram of solution; c) Partial molar enthalpy of solution $\overline{\Delta_{sol} H_{HCl}}$; d) Enthalpy of dilution $\overline{\Delta_{dil} H_{HCl}}$

2.2. Chemical Properties

Hydrogen chloride is thermally stable up to approximately 1500 °C, but appreciable dissociation occurs above this temperature. Completely dry hydrogen chloride is not very reactive: mild steel is not measurably attacked. Moreover, reactions involving dry hydrogen chloride often take place only in the presence of catalysts. In contrast, a solution of hydrogen chloride in a polar solvent is a strong acid and, therefore, an aggressive reagent.

Hydrogen chloride dissolves readily in water, liberating much heat. The enthalpy of solution, (i.e., the total heat of solution $\Delta_{sol} H_{HCl}$), the partial molar enthalpy of solution

$$\overline{\Delta_{sol} H_{HCl}} = \left(\frac{\partial \Delta_{sol} H_{HCl}}{\partial n_{HCl}} \right)_{p,T,n_{H_2O}}$$

and the partial molar enthalpy of dilution

$$\overline{\Delta_{dil} H_{HCl}} = \left(\frac{\partial \Delta_{sol} H_{HCl}}{\partial n_{H_2O}} \right)_{p,T,n_{HCl}}$$

are shown in Figure 9 [9]. The hydrochloric acid formed is a strong and extremely aggressive acid, attacking almost all industrially available metals and alloys to some extent. Metals must, therefore, be protected by an appropriate nonmetallic lining, or nonmetallic materials of construction must be used. Tantalum or highly resistant nickel alloys such as Hastelloy B may be used under precisely defined conditions. Less noble metals dissolve with liberation of hydrogen.

2.3. The HCl–H_2O System

In the HCl–H_2O system at low temperature, four congruently melting solid phases are formed. The corresponding compositions are given by the following formulas: $HCl \cdot H_2O$ (*mp* −15.4 °C), $HCl \cdot 2\,H_2O$ (*mp* −18 °C), $HCl \cdot 3\,H_2O$ (*mp* −25 °C), and $HCl \cdot 6\,H_2O$ (*mp* −70 °C). At higher temperature an important physical property is the solubility of gaseous hydrogen chloride in water and the partial pressure of hydrogen chloride and water over hydrochloric acid at various concentrations and temperatures.

These relationships are shown in Figure 10; they have great practical significance for the absorption and desorption of hydrogen chloride. At lower temperature (below about 100 °C) and pressure (less than about 0.2 MPa), the curves are based on data given in [10], [11]. After careful verification of the original experimental data, these remain the best values available; they are consistent with the partial pressures of hydrogen chloride and water derived from e.m.f. measurements [12]. Values for the high-pressure regions have been determined more recently [13–16] and these can be fitted smoothly to the older values.

Figure 10. Vapor–liquid phase diagram in the $HCl–H_2O$ system
Temperature (°C) is shown for each isotherm. The two-phase region is delimited from the gas phase by the broken lines (- - - -) and from the liquid phase by the continuous lines (——). Curve A–A′ connects the azeotropic points; B–B′ is the critical segregation curve above the critical point of water (point B: 374.1 °C, 21.43 MPa)

The system has a vapor pressure minimum (azeotrope) whose position shifts toward lower hydrogen chloride concentration with increasing pressure and temperature. At 101.3 kPa, the azeotrope, *bp* 108.6 °C, contains 20.4 wt % hydrogen chloride. When the hydrogen chloride concentration is lower than that, the vapor has a higher water content than the liquid with which it is in equilibrium. In this case it is not possible to produce pure anhydrous hydrogen chloride by simple distillation. If the concentration of the acid exceeds that of the azeotropic mixture, however, dry hydrogen chloride can be isolated by distillation. The expense of distillation decreases with increasing hydrogen chloride concentration of the acid.

The hydrogen chloride gas phase coexisting with concentrated hydrochloric acid of more than 35 wt % has a very low water content. A corollary of this is that the moisture content of hydrogen chloride gas must be kept very low to prevent condensation of aqueous hydrochloric acid, which would cause corrosion problems in steel pipes and equipment. At higher pressure and lower temperature, the permissible moisture content must be even lower. Limiting concentrations are given in Table 2. For example, hydrogen chloride gas in steel pipes at 0.5 MPa and 30 °C may contain up to 800 ppm (by volume) of water, but at 0 °C the tolerable water content is < 100 ppm.

At higher pressure and below the critical temperature of hydrogen chloride, the $HCl–H_2O$ system has a miscibility gap, i.e., highly concentrated hydrochloric acid coexists with liquid hydrogen chloride. For example, at 0 °C and > 2.4 MPa, 64 % hydrochloric acid is in equilibrium with anhydrous liquid hydrogen chloride. At lower pressure, hydrogen chloride becomes a gas, and the equilibrium concentration of hydrochloric acid decreases with decreasing pressure. With increasing temperature, the width of the miscibility gap increases, and above the critical temperature of hydrogen chloride, the liquid hydrogen chloride phase is no longer present. Hydrochloric acid remains as the only homogeneous liquid phase, whose maximum concentration decreases as the temperature rises: the heterogeneous region simultaneously becomes wider. As soon as the critical temperature of water is exceeded, the liquid phase disappears. Nevertheless, initially a heterogeneous region exists that becomes smaller with increasing temperature. This region consists of two immiscible gas phases in equilibrium: at 50 MPa and 400 °C, gaseous water containing approximately 13 % hydrogen chloride is in equilibrium with hydrogen chloride containing approximately 35 % water.

The *density* of aqueous hydrochloric acid for the temperature range 0 – 100 °C is given in Table 3.

The *specific heat* c_p decreases with increasing concentration. Some values (at 20 °C) follow:

HCl content, wt %	16	20	24	28	32	36	40
c_p, $J\,g^{-1}\,K^{-1}$	3.11	2.93	2.78	2.65	2.55	2.47	2.40

The temperature dependence of c_p for the acid is considerably greater than that for water. In the above concentration range and at 0 – 100 °C, it is given by the following equation:

$$\left(\frac{\Delta c_p}{\Delta T}\right) = 4.2 \times 10^{-3}\,J\,g^{-1}\,K^{-2}$$

Table 2. Mole fraction ($\times 10^6$) of water in hydrogen chloride gas in equilibrium with concentrated (saturated) hydrochloric acid (based on the results of Kao [13])

p, MPa	Temperature, °C							
	−10	0	10	20	30	40	50	60
0.1	60	440	870	2400	4500	9200	15 500	30 000
0.2	35	230	430	720	3200	6100	10 300	19 000
0.5	18	96	180	350	800	2000	3 900	7 500
1.0	10	60	120	240	430	700	2 200	4 400

Table 3. Density of hydrochloric acid, in grams per cubic centimeter, as a function of temperature

HCl concentration, wt %	Temperature, °C						
	0	10	20	30	50	75	100
5	1.0266	1.0253	1.0230	1.0200	1.0120	0.9993	0.9841
10	1.0521	1.0501	1.0473	1.0440	1.0359	1.0234	1.0090
20	1.1065	1.1022	1.0979	1.0933	1.0839	1.0711	1.0575
30	1.1611	1.1551	1.1493	1.1433	1.1318	1.1175	1.1030
35	1.1875	1.1805	1.1738	1.1671	1.1540	1.1379	1.1220

The *viscosity* η is considerably higher than that of pure water. For 10 wt % acid, the viscosity varies with temperature as follows:

t, °C	0	10	20
η, mPa · s	1.89	1.45	1.16

The variation of viscosity with acid concentration is given below (20 °C):

HCl, wt %	10	20	30
η, mPa · s	1.16	1.36	1.70

The *thermal conductivity* λ is considerably lower than that of water. For 30 % hydrochloric acid, it is 4.6×10^{-5} W m^{-1} K^{-1} (30 °C), compared with 6.18×10^{-5} W m^{-1} K^{-1} for water.

3. Production

Free hydrogen chloride occurs naturally only in low concentration; it has been detected in the stratosphere at levels of ca. 10^{-11} vol % [17]. Inorganic chlorides, however, are widely distributed, chlorine being the eleventh chemical element in order of abundance. Alkali-metal and alkaline-earth chlorides, in particular rock salt, are the primary raw materials for all routes to hydrogen chloride or hydrochloric acid production including those involving intermediate products such as chlorine or chlorinated organic compounds.

In nature, hydrogen chloride is liberated in volcanic eruptions or other releases of subterranean gas. The amount of hydrogen chloride produced can be of the same order as that of sulfur dioxide. Hydrochloric acid occurs in the gastric juice of mammals; in the human stomach, the concentration of acid is about 0.1 mol/L.

3.1. Methods of Preparation

Hydrogen chloride can be formed according to the following reactions:

1) Synthesis from elements:

$$H_2 + Cl_2 \longrightarrow 2\,HCl \quad (1)$$

2) Reaction of metallic chlorides, particularly sodium chloride, with sulfuric acid or a hydrogen sulfate:

$$NaCl + H_2SO_4 \longrightarrow NaHSO_4 + HCl \quad (2)$$

$$NaCl + NaHSO_4 \longrightarrow Na_2SO_4 + HCl \quad (3)$$

$$2\,NaCl + H_2SO_4 \longrightarrow Na_2SO_4 + 2\,HCl \quad (4)$$

3) As a byproduct of chlorination, e.g., in the production of dichloromethane, trichloroethylene, perchloroethylene, or vinyl chloride:

$$C_2H_4 + Cl_2 \longrightarrow C_2H_4Cl_2 \quad (5)$$

$$C_2H_4Cl_2 \longrightarrow C_2H_3Cl + HCl \quad (6)$$

4) From spent pickle liquor in metal treatment, by thermal decomposition of the hydrated heavy-metal chlorides:

$$2\,FeCl_3 \cdot 6\,H_2O \xrightarrow{\Delta H} Fe_2O_3 + 3\,H_2O + 6\,HCl \quad (7)$$

5) From incineration of chlorinated organic waste:

$$C_4H_6Cl_2 + 5\,O_2 \longrightarrow 4\,CO_2 + 2\,H_2O + 2\,HCl \quad (8)$$

By far the greatest proportion of hydrogen chloride is now obtained as a byproduct of chlorination (method 3, Eqs. 5 and 6). The degree of purification required depends on the end use. At present, recovery from waste material according to methods 4 and 5 is becoming increasingly important, whereas the amount of hydrogen chloride generated by method 2 is decreasing. Recovery of hydrochloric acid from pickle liquor is described in [18]. Finally, hydrogen chloride can be formed in undesirable reactions such as the hydrolysis of Friedel – Crafts catalysts:

$$AlCl_3 + 3\,H_2O \longrightarrow Al(OH)_3 + 3\,HCl \quad (9)$$

3.2. Industrial Production

3.2.1. From Hydrogen and Chlorine

The simplest method for producing hydrogen chloride is direct synthesis from the elements, which yields a very pure product. The reaction is strongly exothermic; the standard enthalpy of reaction of Equation (1) is $\Delta H_R^0 = -184$ kJ. Mixtures of hydrogen and chlorine are extremely explosive over a wide range of composition, and explosion can often be initiated by light. Care must, therefore, be taken to avoid the occurrence of reactive mixtures of chlorine and hydrogen in industrial processes.

Industrial production involves the use of a burner; chlorine and hydrogen are fed by separate concentric tubes into the combustion chamber. After ignition, the chlorine burns in the hydrogen with a quiet, very hot flame at $> 2000\,°C$. Silica has proved to be a good material of construction for the burner. Cast iron or steel, sometimes water-cooled, or graphite has also been used. The burner is usually located on the bottom of a cylindrical combustion chamber, with the flame directed vertically upward. The combustion chamber is made of steel lined with refractory brick. A cooling section of appropriate size and shape is connected to the combustion chamber.

If the reactants are very moist or otherwise contaminated, corrosion-resistant construction materials such as silica or graphite must be used. Manufacturing plants still in use today, however, are constructed of carbon steel and the hydrogen chloride produced is water-cooled only to a temperature at which aqueous hydrochloric acid cannot condense. The most probable contaminants are moisture in the hydrogen and oxygen in the chlorine, but oxygen compounds such as dichlorine oxide (Cl_2O) or carbon dioxide can also cause problems by the formation of water.

The mixing ratio of the raw material is adjusted according to the intended use of the hydrogen chloride produced. A slight excess of hydrogen or chlorine may be used; it is inadvisable to work with exactly equimolar mixtures because the reaction is not quite quantitative and it is more difficult to avoid explosive mixtures. Control deviations can easily lead to alternation between excess hydrogen and excess chlorine, with explosive mixtures appearing from time to time. Hydrogen in hydrogen chloride is usually less troublesome than chlorine, so that an excess of 1 – 2 % hydrogen is usually employed. Depending on the purity of the raw materials, extremely pure chlorine-free hydrogen chloride can be obtained, with excess hydrogen being the only impurity. This hydrogen chloride can be used to produce very pure hydrochloric acid, or it may be liquefied or supplied directly to the user in steel pipes as a dry gas.

The use of steel for the synthesis furnaces and coolers is a particularly attractive possibility. They can then be operated under elevated pressure, the magnitude is determined only by the pressure of chlorine and hydrogen and the

temperature and pressure in the pipeline. Here the pressure must be low enough, or the temperature high enough, to prevent condensation of aqueous hydrochloric acid (see Fig. 10 and Table 2). The steel furnaces operated at Hüls can each produce 30 – 40 t/d hydrogen chloride. The hydrogen chloride gas is generated at a pressure up to 0.7 MPa, the water content being < 50 ppm (by volume); steel pipes are, therefore, used to convey it from the plant.

Chemically related processes [19] include the reaction of chlorine with carbon (in the form of coke) and water vapor

$$C + 2\,H_2O + 2\,Cl_2 \longrightarrow 4\,HCl + CO_2 \qquad (10)$$

or the reaction of chlorine with sulfur dioxide and water

$$SO_2 + 2\,H_2O + Cl_2 \longrightarrow 2\,HCl + H_2SO_4 \qquad (11)$$

3.2.2. Reaction of Metal Chlorides with Sulfuric Acid

The sulfate process has a high energy consumption. It is, therefore, gradually decreasing in importance compared with other processes, especially organic chlorination, which inevitably produces large amounts of hydrogen chloride as a byproduct. Moreover, the old argument that sulfate–hydrochloric acid provides a product with higher purity no longer holds; byproduct acid can now be purified sufficiently to satisfy even requirements for high quality. Hence, only the most important sulfate–hydrochloric acid process is described here. Further details are given in [20].

The reaction of common salt with concentrated sulfuric acid according to Equation (2) occurs at comparatively low temperature (150 – 300 °C); hydrogen chloride and sodium hydrogen sulfate are formed. The latter reacts with excess sodium chloride at a minimum temperature of 550 – 600 °C, according to Equation (3), forming neutral sodium sulfate. The use of sodium hydrogen sulfate as a starting material (Eq. 3) is quite feasible but has been discontinued because the high temperature (600 – 800 °C) required and the high energy consumption render the process uneconomic.

Sulfuric acid is now the exclusive starting material. In the Mannheim process, sodium sulfate is produced; in the Berlin hydrochloric acid process, sodium hydrogen sulfate.

In the *Mannheim process*, brick-lined externally fired muffle furnaces are used. These contain a stirrer with a scraping action which prevents agglomeration of the pasty mass and also removes the sodium sulfate produced. Hydrogen chloride passes through the side of the muffle and is propelled by a fan to the next stage, the furnace being maintained at a slightly reduced pressure. The mixture of gases exhausted from the furnace contains up to 85 % hydrogen chloride, as well as air, sulfuric acid mist, and fine particles of salt. As a rule, the gas must undergo several purification stages such as filtration through coke and activated carbon, wet scrubbing, or chemical reaction.

The *Berlin hydrochloric acid process* yields considerably purer hydrogen chloride gas than the Mannheim process. The reaction of common salt with sulfuric acid takes place in molten sodium hydrogen sulfate at about 300 °C in cast-iron retorts. Alternatively, potassium chloride can be used, to give hydrogen chloride and potassium hydrogen sulfate. This process has retained some commercial importance because the principal products are the potassium salts formed (i.e., $KHSO_4$ and $K_2S_2O_7$) [21], whereas hydrogen chloride is considered as a byproduct.

Gas from the retorts is more concentrated because the equipment is more leak proof, and less sulfuric acid mist is present as a result of the lower working temperature.

3.2.3. Recovery as a Chlorination Byproduct

By far the largest amounts of hydrogen chloride and hydrochloric acid are produced as byproducts of chlorination. Equation (6) is merely an example of the varied range of industrial chlorination processes. Nevertheless, the major source of hydrogen chloride is the cracking of 1,2-dichloroethane to give vinyl chloride (→ Chlorinated Hydrocarbons). The quantity of hydrogen chloride produced and consumed can be extremely large, in many installations reaching the order of 10 000 m^3/h (16 t/h or 140 000 t/a) and more. Consequently, hydrogen chloride is often fed directly to a chemical plant

which uses it as a raw material; installed storage capacities for hydrogen chloride are usually comparatively small. It is, therefore, essential to operate the plants at a balanced rate of production and consumption. If production problems or market variations affect one of the plants or products, the other plant can only continue to operate if reserve production capacity (normally not fully used) is installed. Buffer storage for liquid hydrogen chloride is used to overcome short-term inbalances in production versus consumption.

Hydrogen chloride produced by organic chlorination can be treated in various ways:

1) simple isolation of the gas by condensing the chlorinated hydrocarbons;
2) isolation and purification of hydrogen chloride by distillation;
3) aqueous absorption of hydrogen chloride.

Condensation of the chlorinated hydrocarbons is used when the presence of residual chlorinated hydrocarbons or other residues from the chlorination process does not cause any problems in the hydrogen chloride, which is fed as a gas. The degree of purification attainable depends on condensation pressure and temperature. One example is the chlorination of chloromethane to dichloromethane; the hydrogen chloride formed is used only to convert methanol to chloromethane, which in turn is used to produce dichloromethane:

$$CH_3Cl + Cl_2 \longrightarrow CH_2Cl_2 + HCl \tag{12}$$

$$CH_3OH + HCl \longrightarrow CH_3Cl + H_2O \tag{13}$$

The chloromethane and dichloromethane content of hydrogen chloride produced according to Equation (12) does not have any adverse effect on the reaction of methanol with hydrogen chloride (Eq. 13).

Fractional distillation of the liquefied gas may be employed if a purer product is required. For example, the gaseous products from the cracking of 1,2-dichloroethane are liquefied and then separated by distillation into vinyl chloride and hydrogen chloride. Liquefaction of these gases by reducing the temperature to extremely low values is uneconomical, so condensation and distillation are carried out at elevated pressure. An advantage of this procedure is that hydrogen chloride gas is produced at a high enough pressure (usually 1 – 2 MPa) for subsequent processing, thereby avoiding the necessity for subsequent mechanical compression of the gas.

Aqueous absorption of hydrogen chloride gives hydrochloric acid as an intermediate product and leads to inevitable problems with construction materials. These problems have become less severe since the introduction of fluoropolymers. In many installations, however, aqueous treatment has been replaced by nonaqueous methods (e.g., fractional distillation). The absorption of hydrogen chloride can be effected with water or 20 wt % hydrochloric acid. The use of water as the absorption medium is appropriate if the primary aim is the production of 30 – 35 wt % hydrochloric acid as the end product. If demand for the latter is insufficient, the 20 % azeotrope is used for the absorption of hydrogen chloride, thereby concentrating the acid to 30 – 35 wt %. The concentrated hydrochloric acid is first purified, if necessary. It is then distilled to give gaseous hydrogen chloride and azeotropic hydrochloric acid. The hydrogen chloride is dried and delivered to the consumer; the azeotrope is recycled to the absorption stage. If the presence of chlorinated hydrocarbons in hydrochloric acid is undesirable, they can be removed by introducing a stripping step. A simplified scheme is shown in Figure 11. A small amount of water is fed to the absorption column to render the gas stream free of hydrogen chloride. A corresponding amount of acid must be separated for other use.

A number of process and equipment parameters are important for assessing the economics of the aqueous absorption of hydrogen chloride from a production gas stream:

1) The concentration of hydrogen chloride in the gas stream determines the pressure and temperature that must be maintained in the absorption column.
2) The energy requirement for liberating pure hydrogen chloride gas decreases with increasing concentration of the concentrated acid formed.
3) Production of concentrated hydrochloric acid from a gas stream with a low hydrogen chloride concentration requires comparatively great effort because either the pressure must be increased, the temperature reduced, or both.

Figure 11. Flow diagram showing recovery of hydrogen chloride as a byproduct of chlorination in aqueous absorption (CHC = chlorinated hydrocarbons)
a) Hydrogen chloride absorption column; b) Chlorinated hydrocarbon stripping column; c) Hydrogen chloride desorption column

4) The presence of a high concentration of water vapor in the production gas stream can, under certain circumstances, render the production of concentrated hydrochloric acid impossible.

Industrial processes have been reviewed by SCHMIDT [10] and VIEWEG [22]. The latter proposes the use of magnesium chloride solution to absorb low levels of hydrogen chloride from gas containing a high level of water vapor.

The choice of *construction materials* for hydrogen chloride absorption equipment is restricted because of the possibility of attack both by concentrated hydrochloric acid and by chlorinated hydrocarbons. Graphite heat exchangers are used to cool the acid. For a long time a special ceramic was the only economically viable material for the pumps. The distillation column is lined with acid-proof bricks or graphite blocks, and the bricks are cemented with phenolic resin. Frequently, a special acid-resistant rubber lining is applied between the steel casing and the brick wall to prevent attack by acid that might penetrate pores and cracks. Vessels and equipment made entirely of phenolic resin are chemically very resistant, but brittle and mechanically fragile, and require support (e.g., by an outer shell of glass-fiber-reinforced polyester resin). This type of equipment is suitable only for operation at atmospheric or possibly slightly higher pressure.

The same is true for the chlorinated hydrocarbon stripping column. If the concentration of chlorinated hydrocarbons is low, or if they have been effectively removed from the acid, other materials such as poly(vinyl chloride) can be used for storage vessels. The desorption column, however, is made of graphite because of the high operating temperature. Alternatively, rubber-lined columns with inner brick linings can be used. Steel columns lined with perfluoropolymer, especially polytetrafluoroethylene (PTFE), have been used with generally excellent results, although differences exist among the products from different manufacturers with regard to microporosity, tear resistance, and flow properties. Compared with graphite columns, coated steel columns have the advantage that they can operate at elevated pressure, but failure of a PTFE lining would lead to rapid destruction of the steel casing. However, these columns can be constructed of fairly small individual elements that may be replaced quickly, reducing maintenance downtime. Heat exchangers are made of graphite in all cases. Another possibility is to use tantalum for lining and evaporators, although special precautions must be taken to avoid embrittlement due to absorption of hy-

drogen. Furthermore, hydrogen fluoride must be absent.

Completely dry hydrogen chloride will not attack steel pipes or compressors. Hydrogen chloride gas was formerly dried by using concentrated sulfuric acid, but another approach is to make use of the properties of the $HCl-H_2O$ system (see Fig. 10 and Table 2). At low temperature, the partial vapor pressure of water over highly concentrated hydrochloric acid is very low; hydrogen chloride can therefore be dried by cooling to sufficiently low subzero temperature. At slightly elevated pressure ($p_{abs} \approx 0.3$ MPa), it is sufficient to attain $-10\,°C$ to give satisfactory results. Hydrochloric acid mist must, however, be removed completely, or severe corrosion can result.

3.2.4. Recovery from Waste Incineration

All chlorination processes produce undesirable chlorinated hydrocarbons in addition to the product desired. These unusable and often noxious substances must be disposed of for environmental reasons. One possibility is incineration to hydrogen chloride, water, and carbon dioxide; the hydrogen chloride should be recovered for both economic and environmental reasons.

Although the methods used vary in detail [23–25], the general principle remains the same. Combustion takes place in a refractory-lined furnace at $> 1000\,°C$. Waste chlorinated hydrocarbons containing up to 70 wt % chlorine normally possess good combustion properties, but any further increase in chlorine content reduces the calorific value to such an extent that fuel oil or gas must be added to support combustion.

Optimum reaction conditions lie within the following limits:

1) Excess oxygen must always be present to guarantee complete decomposition of chlorinated hydrocarbons. The hydrogen chloride gas formed is consequently able to react with this oxygen to form chlorine and water in accordance with the Deacon equation:

$$2\,HCl + 1/2\,O_2 \rightleftarrows Cl_2 + H_2O \qquad (14)$$

The reaction has a negative enthalpy of reaction ($\Delta H_r^0 = -57.1$ kJ/mol) and entropy of reaction ($\Delta S_r^0 = -64.7\,J\,K^{-1}\,mol^{-1}$). With increasing temperature, the equilibrium shifts from right to left, thus favoring formation of hydrogen chloride. The temperature is maintained as high as construction materials permit, to prevent formation of chlorine; even if the partial pressure of water is kept high and the oxygen excess low, a temperature $> 1000\,°C$ is necessary to shift the equilibrium to the left. This keeps the chlorine at an acceptable level and also ensures complete combustion.

2) Reaction temperature must not exceed $1200\,°C$ to prevent formation of nitrogen oxides, which would contaminate the hydrochloric acid product and, which is worse, cause waste gas purification problems. A possible solution is to use pure oxygen instead of air [16].

For these reasons, incineration of waste chlorinated hydrocarbons is carried out between 1000 and $1200\,°C$. Cooling the flue gases combined with steam generation can cause problems with construction materials. The absence of corrosive combustion products must, therefore, be assured. The treated wastes should have a well-known composition (down to trace contaminants) for proper prediction of the expected combustion products, their concentration, and behavior. Slow cooling can cause chlorine to reform, so rapid cooling is preferred.

Hydrogen chloride is recovered from the combustion gases by absorption, i.e., the process is similar to that used in recovery from chlorination processes, except for the following:

1) A dry process is impossible because water vapor is always present.
2) The gases should be condensed in such a way as to form the most concentrated hydrochloric acid possible so that gaseous hydrogen chloride or concentrated hydrochloric acid can be obtained. Dilute hydrochloric acid has little commercial value.
3) Special corrosion problems must be overcome at places of possible, but not necessarily regular, acid condensation.
4) If the gaseous combustion products are used directly, the operating temperature must always be kept above the condensation temperature of hydrochloric acid.

One of the oldest plants producing commercial quantities of 33 wt % hydrochloric acid by incinerating chlorinated hydrocarbons is that of Atochem at St. Auban in the south of France [25]. This plant opened in 1975 and consumes approximately 16 000 t of chlorinated hydrocarbons material per year. Many additional chlorinated hydrocarbon incineration plants have since been built, and the hydrochloric acid produced is finding a wider range of uses (e.g., addition to ethylene) [27].

3.3. Purification

Many impurities in hydrogen chloride gas (e.g., SO_2, As, and Cl_2) can be removed by adsorption on activated carbon [28]. As the importance of the sulfate process decreases, the removal of chlorinated hydrocarbons from hydrogen chloride gas or hydrochloric acid is of greater practical relevance. Gaseous hydrogen chloride can be purified by low-temperature scrubbing with a high-boiling solvent, which may be another chlorinated hydrocarbon (e.g., hexachlorobutadiene or tetrachloroethane), or special oil fractions. The use of activated carbon is often unnecessary after such treatment. Chlorine may be removed with carbon tetrachloride, in which it is much more soluble than is hydrogen chloride gas.

Hydrochloric acid, used as such or for generation of hydrogen chloride, contains mainly volatile impurities such as chlorinated hydrocarbons. In these cases the impurities may be removed from the acid by stripping (see Fig. 11). Stripping with an inert gas stream, which results in lower energy consumption, is possible, although in most cases heating of the gas is preferable for environmental reasons. Inorganic impurities, in particular iron, are removed by ion exchange.

4. Quality Specifications

The quality specifications for *gaseous hydrogen chloride* depend on intended use. There are no general quality standards. Only a trace (a few parts per million) of water is usually permitted, particularly if the gas is to be compressed and liquefied. Dry hydrogen chloride does not attack iron; thus, steel equipment and pipelines can be used. Hydrogen chloride gas is regarded as dry if no danger exists of hydrochloric acid condensation at operating temperature and pressure.

Hydrochloric acid has no generally accepted quality specification. In the Federal Republic of Germany, the only official standard is DIN 19 610 (November 1975), which gives the following specifications for hydrochloric acid for boiler feed water treatment:

Hydrogen chloride content ≥ 30 wt %
Sulfate (SO_4^{2-}) content ≤ 0.5 wt %
Iron (Fe^{3+}) content ≤ 0.002 wt %
Content of organic chlorine compounds (expressed as
Cl^-) ≤ 0.02 g/L

Quality requirements for medicinal use are given in DAB 9 [29] for both concentrated (36 wt %) and dilute (10 wt %) hydrochloric acid. Prescribed purity tests include free chlorine (4 ppm), arsenic (2 ppm), heavy metals (2 ppm), sulfate (20 ppm), and residue on evaporation (0.01 %). Other countries have their own regulations [30].

5. Storage and Transportation

Wrought- and cast-iron, steel, and steel alloys have good resistance toward dry hydrogen chloride gas or liquid. Steel is, therefore, suitable for equipment and containers up to 280 °C, including pressure vessels used for storage and transportation of dry hydrogen chloride.

Even traces of moisture significantly increase the corrosion rate, and alloyed austenitic steels become liable to stress crack corrosion. If the working temperature cannot be raised above the condensation point, either nonmetallic materials or more exotic metals must be used, such as nickel–molybdenum alloys with high molybdenum content, zirconium, niobium, tantalum, or noble metals such as gold or the platinum-group metals. In practice, it is imperative to specify precisely the operating limits for metals to be used with hydrochloric acid or moist hydrogen chloride. In all cases, limits are given for acid concentration or temperature. Contamination with oxidizing or complexing agents must be avoided. Traces of fluoride ions in hydrochloric acid, for example, can lead to rapid corrosion

of zirconium or tantalum, although tantalum has proved suitable for hydrochloric acid distillation columns in the absence of damaging impurities.

A wide choice of nonmetallic construction materials is available. For high temperature, ceramics, graphite, or polytetrafluoroethylene may be suitable. Phenolic resins are used as cement for brick lining. At lower acid concentration (below 25 %), enameled or glass apparatus can be used. At lower temperature, (e.g., for storage and transportation), vessels may be made of rubber-lined steel, polyolefin, or poly(vinyl chloride), the latter usually with glass-fiber reinforcement. If the acid contains traces of chlorinated hydrocarbons such as dichloromethane, vessels fabricated in, or lined with, phenolic resin are preferred. Plastics such as poly(vinyl chloride) and polyethylene can withstand use for several years.

For transportation of hydrochloric acid and liquefied hydrogen chloride, special labels must be used that comply with the international regulations for transportation of hazardous goods:

Hydrochloric acid:	Hazard code number 80 UN no. 1789 Warning sign 8 (causes burns) CFR 49: 172.101 Cor. M RID/ADR, class 8, no. 5 b
Hydrogen chloride:	Hazard code number 286 UN no. 1050 Warning signs 6.1 (poisonous) and 8 (causes burns)

6. Uses and Economic Aspects

Hydrochloric acid and hydrogen chloride are two of the most important basic industrial chemicals.

The largest proportion of *hydrogen chloride* is used immediately by the producer himself, because the hydrogen chloride byproduct of organic chlorination processes has to be used as completely as possible. This is done by means of oxychlorination or hydrochlorination, or to a small extent, recovery of chlorine (e.g., by the KEL process, a modified Deacon process [31] or by electrolysis of hydrochloric acid [32]).

Aqueous hydrochloric acid has many uses as a strong inorganic acid: manufacture of chlorides, dissolution of minerals, pickling and etching of metals, regeneration of ion-exchange resins for water treatment, neutralization of alkaline products or waste materials, acidification of brine in chlor-alkali electrolysis, and many others.

Hydrochloric acid and hydrogen chloride production figures for various countries are given in Table 4.

7. Toxicology and Occupational Health

Hydrogen chloride causes severe irritation of the eye and respiratory tract and, to a lesser extent, the skin. The vapor can produce keratoconjunctivitis. Inhalation causes irritation and damage to mucous membranes. Hydrogen chloride is usually detectable by odor at 1 – 5 ppm and becomes objectionable at 5 – 10 ppm. Prolonged occupational exposure to excessive hydrogen chloride concentration causes increased incidence of chronic bronchitis or stomach and intestinal disorders due to abnormal acid levels. Increased incidence of a characteristic dental decay has also been observed with prolonged exposure, even at apparently tolerable levels. A concentration > 10 ppm is strongly irritating, even when some acclimatization has occurred [33].

Suitable protective goggles should be worn by personnel working with hydrochloric acid; the use of protective clothing, rubber gloves, and rubber boots is recommended. Inhalation of the vapor should be avoided. The respirator filter for inorganic gases is suitable (in the Federal Republic of Germany, code letter B, code color gray), as is the hydrogen chloride and sulfur dioxide filter (code letter E, code color yellow [34]).

In the Federal Republic of Germany, hydrogen chloride and hydrochloric acid (> 10 wt %) are controlled by the Verordnung über gefährliche Stoffe (GefStoffV, regulations for the control of dangerous substances), which have been adjusted to the corresponding directives of the EEC [35]:

1) Anhydrous hydrogen chloride: hazard symbol C (corrosive). Hazard information ("R" notices): 35 (causes serious burns); 37 (causes irritation of respiratory tract). Safety Instructions ("S" notices): 7/9 (keep containers tightly closed and store in a well-ventilated place); 26 (on contact with the eye,

thoroughly wash with water and seek medical advice).

2) Hydrochloric acid containing over 25 wt % hydrogen chloride: hazard symbol C (corrosive, causes burns).“R” notices: 34 (causes burns); 37 (see above).“S” notices: 2 (keep away from children), 26 (see above).
3) Hydrochloric acid with 10 – 25 wt % hydrogen chloride: hazard symbol X_i, irritant.“R” notices: 36/38 (causes eye and skin irritation)“S” notices: 2 (see above), 28 (on contact with the skin, immediately wash with copious amounts of water).

In the event of skin or eye contact, the affected area should be rinsed immediately and thoroughly with a large amount of water. Contaminated clothing should be treated similarly, and alkaline cleansing solution may also be used. For work with hydrogen chloride, especially at elevated pressure, breathing apparatus with an independent air supply and full protective clothing must be readily available in case of accident.

In the Federal Republic of Germany, the MAK value for hydrogen chloride is 5 ppm by volume, corresponding to 7 mg/m^3 [36]. The same values are valid as TLV in the United States. In the Soviet Union 3 ppm (5 mg/m^3) has been established.

In clean air regulations (TA Luft, 1986), concentration limits for hydrogen chloride in the atmosphere are 0.1 mg/m^3 as an annual average and 0.2 mg/m^3 for short periods. Phytotoxicological investigation has shown that plants have differing tolerances [37–39]. According to guidelines issued by the VDI, 2310 sheet 4, sensitive vegetation such as lettuce, strawberries, spruce, birch, and apple trees should not be exposed to a hydrogen chloride concentration higher than 0.8 mg/m^3 as a daily average or 0.1 mg/m^3 as a monthly average.

The concentration of hydrogen chloride in industrial waste gases must (according to regulations in the Federal Republic of Germany) normally not exceed 30 mg/m^3, although the limit is 50 mg/m^3 for waste incineration plants; the cost of gas cleaning can, therefore, vary considerably. A simple water scrubbing operation is often sufficient, but more than one stage may be necessary, sometimes including a final scrubbing with an alkaline solution. In many cases it is not possible to produce a commercial hydrochloric acid. The dilute acid is then neutralized before being discarded in the wastewater. Neutralization with caustic soda occasionally results in a salt solution that is pure enough to be recycled to a chlorine plant.

1. History

In the middle ages PARACELSUS is reported to have noted that a gas is yielded when iron is dissolved in the “spirit of vitriole”. TURQUET DE MAYERNE (1573 – 1655) noted that this gas was inflammable. However, hydrogen was first separated and identified in the second half of the 18th century; BOYLE produced “facticious air” from diluted sulfuric acid and iron.

CAVENDISH (1731 – 1810) proved that there were different types of air, one of which was “inflammable air” and that a number of metals, when dissolved in acid, produced various amounts of this gas. In 1766, he published precise values for the specific weight and density. During the late 1770s, he made experiments with electrical discharges in a hydrogen – oxygen mixture thereby producing water.

In 1785, LAVOISIER, demonstrated the splitting of water into hydrogen and oxygen in a heated copper tube. He also gave the “inflammable air” the name hydrogen.

Chronology of Further Significant Events

1800. First production of hydrogen and oxygen by electrolysis (NICHOLSON and CARLYLE)
1898. Liquefaction of hydrogen using the Linde process (J. DEWAR)
1902. First commercial electrolysis installation by OERLIKON
1929. Production of pure para-hydrogen (K. F. BONHOEFFER, P. HARTECK)
1931. Discovery of the hydrogen isotope deuterium (H. C. UREY)
1935. Synthesis of “superheavy hydrogen”, tritium, through neutron bombardment of deuterated phosphoric acid (P. HARTECK, OLIFANT, E. RUTHERFORD)
1954. Ignition of the first hydrogen bomb on the Bikini Atoll (USA)
1955. Description of the utilization of hydrogen as energy carrier medium (JUSTI)
1969. Development of an overall hydrogen energy concept using the favorable properties of hydrogen and including non-conventional energy systems (J. O. M. BOCKRIS, D. P. GREGORY, C. MARCHETTI, T. N. VEZIROGLU, and others)
1986. The total hydrogen production worldwide amounts to 500×10^6 m^3 (STP)/a. U.S. hydrogen production and consumption is about 8×10^6 t.

Hydrogen in Transportation. The buoyancy of hydrogen quickly lead to the use of this gas in balloons (C. CHARLES, 1783), but the use for aeronautics was ended by the HINDENBURG disaster at Lakehurst in 1937. Experiments using hydrogen as an *engine fuel* had already been carried out in 1820 by W. CECIL. These experiments were followed by investigations in car engines up until the Second World War and partly afterwards (RICARDO, BURSTAL, ERREN). Various transport systems using hydrogen were tested, e.g., in the United States by R. BILLINGS or in the Federal Republic of Germany (Daimler Benz, BMW) in the last decade.

The potential of hydrogen as an *aviation fuel* was established 1957 with the lift-off of a hydrogen-powered B-57 twin-engine jet bomber. From 1963 on liquid hydrogen –liquid oxygen propelled rockets were launched. For the Apollo moon flights 12×10^6 L of liquid hydrogen were necessary to tank the Saturn carrier rockets.

2. Properties

Hydrogen (hydrogenium, *ὑ δ ω ῏* = the water, *γ ε ν ν ε ι ν* = to give birth) [12 385-13-6] H, A_r 1.00 797, atomic number 1, is the first element in the periodic table, having the electron configuration 1 s^1. It has usually the oxidation state +1, but in salt-type hydrides –1 is also possible. Three isotopes with A_r 1, 2 and 3 are known; the isotope with A_r 3 is unstable. The differences in the relative isotopic masses are large so that physical and kinetic properties can differ considerably. The isotope with the relative mass 2 is named *deuterium* [16873-17-9] (symbol D), that with the mass 3 *tritium* [15 086-10-9] (symbol T). The atomic nuclei, all with a single positive charge, are given the names *proton, deuteron*, and *triton.*

With the expected increasing significance of hydrogen as a universal chemical and as an energy carrier, its physical and thermodynamic properties have undergone further extensive investigations. The compilation given here is an excerpt; comprehensive data can be found in various summaries and other literature, e.g., in [1-8].

2.1. Physical Properties

2.1.1. *General Physical Data*

The *atomic radius* of the free hydrogen atom is 53 pm, the *covalent atomic radius* of hydrogen in crystal structures is between 30 and 35 pm. The length of the H – C bond in saturated hydrocarbons is ca. 112 pm, in water vapor the H – O bond has a length of 96 pm. The isotopes H, D and T form diatomic molecules, the combinations being H_2, [1333-74-0], D_2 [7782-39-0], T_2 [10028-17-8], HD [13983-20-5], HT [14 885-60-0] and DT [14885-61-1]. Atomic and molecular data are given in Table 1.

Table 1. Atomic and molecular data of hydrogen and hydrogen isotopes

Ortho- and Para-Hydrogen. The atomic nuclei of hydrogen and its isotopes possess a spin, the value of which is 1/2 for H and T, and 1 for D. In the diatomic molecules both atomic nuclei can either rotate in the same or in opposing direction, i.e., parallel or anti-parallel. The molecules H_2, D_2 and T_2 can therefore exist in the form of two isomers with different nuclear spin, namely in the ortho-form (parallel nuclear spin) and in the para-form (anti-parallel nuclear spin); the two forms are interconvertible and in equilibrium with each other. This effect can be observed in all homonuclear diatomic molecules in which the nuclei have spins, but in the case of hydrogen the effects on properties are most pronounced. The following forms can be distinguished:

o-H_2 ortho-hydrogen

p-H_2 para-hydrogen

e-H_2 equilibrium hydrogen

n-H_2 normal hydrogen

e-H_2, e-D_2 and e-T_2 all correspond to mixtures of the equilibrium concentration of *definite* temperatures. n-H_2 (n-D_2, n-T_2) is a mixture of the equilibrium concentration at *ambient* temperature, i.e., 25 mol % p-H_2 or p-T_2 and 75 % o-H_2 or o-T_2. n-D_2 contains 33.33 % p-D_2 and 66.67 % o-D_2.

The conversions o-H_2 to p-H_2 and o-T_2 to p-T_2 are exothermic; both equilibrium composition and heat of conversion are a function of temperature, but independent of pressure (see Figs. 1 and 2).

Figure 1. Equilibrium composition for the conversion of o-hydrogen – p-hydrogen

Figure 2. Heat of conversion of o-hydrogen – p-hydrogen

For D_2 the ortho : para relation is different to that of H_2 and T_2. The conversion *p*-D_2 to o-D_2 is exothermic so that at low temperatures the ortho – form is prevalent, e.g., at 20 K 99.52 %.

The ortho – para equilibrium is attained very slowly in the gaseous phase (see Fig. 3), but more rapidly in the condensed state (see Chap. Liquefaction of Hydrogen). The conversion of deuterium is slower than that of hydrogen, but tritium reacts more rapidly than H_2. Solid tritium, for example has a conversion rate 210 times faster than solid hydrogen. The conversion rate can be increased in the presence of catalysts or magnetic fields. The hydroxides of Fe (III), Co (III), Ni (II), Cr (III), Mn (IV) or active charcoal are effective as catalysts [9], [10]. Apart from strong homogeneous magnetic fields, the inhomogeneous magnetic fields of paramagnetic substances, electrical discharges as well as thermo and photochemical activation increase the conversion rate.

Figure 3. Self conversion of o-hydrogen to *p*-hydrogen in absence of catalysts as a function of time

Thermodynamic Properties. The differences in the masses of the isotopes are relatively large, so that thermodynamic properties differ considerably. Small differences are also found among the spin-spin isomers so that for certain purposes attention must be paid to the actual form present. At low temperature *p*-H_2, *o*-D_2 or *p*-T_2 can be present in a virtually pure state. The properties of *n*-H_2 (o – p isomerization prevented by rapid cooling) are also known at low temperatures.

Hydrogen gas is colorless, non-poisonous, odorless and tasteless. At 0 °C and 100 kPa 1 L of H_2 has a mass of 0.0898 g. The most important properties of n-H_2 and p-H_2 are given in Tables 2-4, and Figure 4.

Figure 4. Vapor pressure of n-hydrogen and p-hydrogen

Contrary to most other gases, the *inversion temperature* of hydrogen lies below ambient temperature. The temperature, at which the negative Joule – Thomson coefficient μ (heating by expansion) changes to a positive μ (cooling by expansion), can be seen from the Joule – Thomson inversion curve (Fig. 5). A cooling effect is obtained only when the decompression takes place from a state which is characterized by a point below the inversion curve.

Figure 5. Joule – Thomson inversion curve for p-hydrogen with vapor pressure curve

Liquid hydrogen is a colorless, very mobile liquid with low viscosity and surface tension. Some properties are given in Tables 2 and 4.

Solid hydrogen is colorless and crystallizes in the hexagonal closest-packed structure. Data for p-H_2 are: a = 375 pm, c/a = 1.633, molar volume 22.56 cm^3/mol [11]. At higher pressure several phase transitions occur [12]. Under extremely high pressure (ca. 2 – 3×10^{11} Pa) a metallic, electrically conductive hydrogen phase with a density of >1.000 kg/m^3 has been reported [13-15]. Some properties of solid p-H_2 at the triple point are presented in Table 5.

Table 5. Properties of solid p-hydrogen at triple point (7.04 kPa, 13.803 K)

Density, kg/m^3	86.50
Heat of fusion, J/mol	117.5
Heat of sublimation, J/mol	1022.9

Dielectric constant	1.286

2.1.2. *Solubilities, Diffusion Properties and Evaporation Equilibria*

Solubility of Hydrogen in Liquids. Hydrogen is only slightly soluble in liquids. In contrast to the highly-soluble gases, however, the solubility generally increases with increasing temperature. Examples for the solubility in *nonaqueous solvents* are given in Table 6 and Figure 6.

Table 6. Solubility of hydrogen in nonaqueous solvents

Solvent	*t*, °C	*p*, [a] MPa	Solubility, mol %
Hexane	0	0.1	5.82×10^{-2}
Benzene	20	0.1	2.47×10^{-2}
Diethylether	0	0.1	5.29×10^{-2}
Ethanol	0	0.1	1.8×10^{-2}
Carbon tetrachloride	0	0.1	2.60×10^{-2}

Gas oil	25	10	0.274 [d]

[a] Partial pressure of hydrogen.
[b] Density 0.8003 g/cm^3, vapor pressure 10.7 kPa (25 °C).
[c] Density 0.8319 g/cm^3, vapor pressure 0.3 kPa (25 °C).
[d] Moles per kilogram solvent

Figure 6. Solubility of hydrogen in various liquids (hydrogen pressure 10 MPa)

a) N_2; b) CO; c) Ar; d) O_2; e) CH_4; f) C_2H_4; g) C_2H_6; h) C_3H_6; i) C_4H_{10}; j) C_6H_{14}; k) CO_2

The water solubility has a minimum at ca. 50 °C and then increases again with increasing temperatures (see Table 7). Electrolytes lower the water solubility because of the salt effect.

Table 7. Solubility of hydrogen in water at a hydrogen pressure of 101.3 kPa [17]

T, K	Solubility, 10^3 mol %	Ostwald – coefficient $\times10^2$
273.15	1.755	2.184
283.15	1.576	2.032

293.15	1.455	1.940
303.15	1.377	1.893
313.15	1.330	1.883
323.15	1.310	1.905
333.15	1.312	1.957
343.15	1.333	2.037
353.15	1.371	2.144

Because of the reduced volatility, deuterium, tritium, and their various interisotopic compounds have a somewhat greater solubility than the comparable hydrogen compounds. The relative differences in solubility amount to a few percent only (close to the accuracy of measurement) and diminish with increasing temperature.

Solubility of Hydrogen in Metals. Metals, with not completely occupied inner electron levels, have a particularly high solubility potential for hydrogen. Hydrogen is dissolved in metals not in the molecular but in the atomic form, whereby *non-stoichiometrical* (alloy-type) or *stoichiometrical* (partly hydride-type) compounds may be formed.

The solubility of hydrogen in metals at small hydrogen concentrations is proportional to the root of the hydrogen partial pressure (Sievert's law). The hydrogen solubility decreases with increasing temperature. Hydrides can be decomposed thermally.

Palladium and palladium – silver alloys with a silver content <40 wt % have a particularly high solubility potential for hydrogen. The hydrogen atoms give their electrons to the electron gas of the palladium metal and occupy interstitial sites of the metal crystal structure. Palladium can absorb 2800 times its own volume of hydrogen. Figure 7 shows isotherms for hydrogen in palladium. They are similar to the Van der Waals isotherms of real gases. For an explanation of the so-called plateau dissociation pressure see Section Hydrogen-Energy Conversion Systems.

Figure 7. Pressure – composition isotherms for hydrogen in palladium [19]

The solubility of the hydrogen isotopes in palladium decreases in the order H > D > T; with group 5 metals (V, Nb, Ta), however, the solubility increases in this order. This effect is explained by differences in the vibration energies of the metal structure (in palladium: octaeder holes are occupied; in group 5 metals: tetraeder holes are occupied).

Impurities in the metal and in the hydrogen can lower the solubility or cancel it completely. Especially carbon monoxide, hydrogen sulfide and oxygen are poisonous with this respect.

Dissolved hydrogen in metals influences their mechanical properties (hydrogen embrittlement, see Section Materials), magnetic properties (reduction of the paramagnetism of Cr and Ti) and can cause superconductivity. For example, nonsuperconductive palladium becomes superconducting if hydrogen is added, to the extent of $PdH_{0.8}$. The transition temperature of $PdH_{1.0}$ is 8.8 K, that of $PdD_{1.0}$ 10.7 K, whereas $Pd_{0.55}Cu_{0.45}H_{0.7}$ even has a transition temperature of 17 K.

The absorption of hydrogen in metals and metal alloys has become important for the storage of hydrogen in hydride storage systems. An overview of hydrogen in metals is given in [20] and [21] (⟶ Hydrides, see Section Hydrogen-Energy Conversion Systems).

Solubility of Gases in Liquid Hydrogen. With the exception of helium all gases are solid at the temperature of liquid hydrogen. In liquid hydrogen they are soluble only in traces: oxygen (32 – 26 K) <0.5 ppm; nitrogen (32 K) ca. 15 ppm, (20.4 K) <0.1 ppm.

The solubility of helium in liquid hydrogen at 1 MPa is shown in Figure 8: In the range of 16 – 26 K it increases from 0.5 to 3 mol % and then decreases at higher temperatures.

Figure 8. Solubility of helium in liquid hydrogen (pressure 1 MPa)

• liquid concentration He

Vapor – Liquid Equilibria. Various vapor – liquid equlibrium systems exist at low temperature. However, only the isotope mixtures, e.g., H_2 – HD, or H_2 – D_2 show simple boiling point diagrams with only little deviation from the ideal behavior. The vapor pressures of the mixture H_2 – HD, e.g., deviate 4 % at the most from that of an ideal mixture [22], [23].

Two- and multicomponent mixtures with nitrogen, carbon monoxide and methane are important in low-temperature processes for separation or purification of hydrogen. In these mixtures the hydrogen in the hydrogen-poor liquid phase is supercritical. Low hydrogen contents in the coexistent liquid can only be reached in the neighborhood of the melting point of the non-hydrogen components.

Figure 9 shows the hydrogen equilibrium concentrations in the liquid and the gas phase in the systems H_2 – CO and H_2 – N_2 [17], [18].

Figure 9. Vapor – liquid equilibria of the systems H_2 – N_2 (A) and H_2 – CO (B)

Isotherms show (clockwise from left to right) the composition of the liquid phase, the critical pressure at the maximum of the isotherm, and the composition of the gas phase as a function of pressure (concentrations in mol %)

The system H_2 – Ne shows a complicated behavior. Figure 10 shows a *p*-*x*-diagram for the composition range in which a miscibility gap in the liquid phase occurs: If a mixture with the composition x_1, is compressed isothermally, first two two-phase regions, each with a different liquid-phase composition are found. Then a one-phase region (a hydrogen-rich liquid phase) is reached. At the composition x_2 only one two-phase liquid system exists. At the composition x_3 an azeotropic mixture is formed, the liquid phase has the same composition as the gas phase. Equilibrium compositions of the system H_2 – Ne are given in [16].

Figure 10. Sketch of a typical isotherm in the range of existence of a miscibility gap of the system n-H_2 and Ne [16]

(V = vapor phase, liq. 1 = hydrogen-rich liquid phase; liq. 2 = neon-rich liquid phase)

Diffusion Properties. Hydrogen is the element with the highest diffusion capacity. Some diffusion coefficients of hydrogen in gases and liquids are given in Table 8. For further values see [1], [4], [24], [25]. In metals with a high hydrogen solubility usually a high hydrogen diffusion coefficient is also found, e.g., in palladium 5×10^{-7} cm^2/s and in vanadium 5×10^{-5} cm^2/s (at 25 °C). These values are in the same range as the diffusion coefficient of hydrogen ions in water (ca. 10^{-4} cm^2/s).

Table 8. Diffusion coefficients of hydrogen in gases (pressure 100 kPa) and liquids

Diffusion in	*t*, °C	*D*, cm^2/s

N_2	0	0.674
O_2	0	0.701
H_2 (selfdiffusion)	0	1.285
H_2O, vapor	0	0.759
H_2O, liquid	25	4.8×10^{-5}
Iron, smelting	1600	5.64×10^{-3}
Aluminum, smelting	960	1.28×10^{-5}

2.2. Chemical Properties

The first electron shell can be filled with a maximum of two electrons. Therefore, the chemistry of hydrogen depends mainly on three processes, (1) loss of the valency electron to yield the hydrogen ion, H^+; (2) gain of an electron to form the hydride ion, H^-, and (3) formation of an electron pair bond. The degree of covalent: ionic character of this bond depends on the electronegativity of the element to which hydrogen is attached. The electronegativity of hydrogen according to PAULING is 2.1. Except in the hydrogen molecule itself, where the bond is homopolar, all H – X bonds will possess some polar character.

Hydrogen is not exceptionally reactive, although hydrogen atoms react with one another and with all other elements with the exception of the noble gases (only with helium short-lived instable forms such as HeH^+ and HeH_2^{2+} are known). Hydrogen oxidizes less electronegative elements (e.g., alkali and alkaline earth metals), and reduces more electronegative ones (e.g., halogens, oxygen, nitrogen, carbon).

The strength of the H – X bond in covalent hydrides depends on the electronegativity and size of the element X. The bond strength decreases in a group with increasing atomic number and generally increases across any period. The most stable covalent bonds are those formed between two hydrogen atoms (or isotopes), or with halogens, oxygen, carbon, and nitrogen. The average values for the bond energy are given in Table 9.

Table 9. Average bond-dissociation energies of representative covalent hydrogen bonds at 298 K

Bond	kJ/mol	Bond	kJ/mol
H–H	428.2	H–N	314
H–D	440	H–N=	435.4
D–D	443.4	H–O	428.2
T–T	446	H–OH	498.1
$H–CH_3$	435.3	H–S	344.5
H–C=	452	H–Cl	431.6
H–C≡	536	H–F	568.9

Halogens react with hydrogen to yield hydrogen halides, with increasing reactivity in the sequence iodine, bromine, chlorine, and fluorine. At –210 °C liquid fluorine ignites immediately in hydrogen; solid fluorine explodes violently in the presence of liquid hydrogen; similarly, combined hydrogen reacts more or less violently with fluorine. Chlorine and bromine also react explosively with hydrogen on excitation by heat or ultraviolet radiation (chlorine hydrogen reaction). Fluorine, chlorine, and bromine react with hydrogen in a radical chain reaction:

initiation reaction

$$\mathrm{Hal_2} \rightarrow 2\,\mathrm{Hal}\cdot$$

propagation reactions

$$\mathrm{Hal}\cdot + \mathrm{H_2} \rightarrow \mathrm{H}\cdot + \mathrm{HalH}$$

$$Hal_2 + H\cdot \rightarrow HHal + Hal\cdot$$

Oxygen reacts with hydrogen according to

$$H_2 + 1/2\,O_2 \rightarrow H_2O \quad \Delta H^0_{298} = -286.02\,kJ/mol$$

Above 550 °C the reaction occurs with flame propagation, explosion or detonation (oxyhydrogen reaction). The flame temperature is limited by the thermal dissociation of water vapor and attains a maximum of 2700 °C. For the explosion limits in air or oxygen see Section Ignition and Detonation Performance.

At elevated temperatures in presence of suitable catalysts, hydrogen will react with *nitrogen* to form ammonia. Industrially this is one of the most important reactions (⟶ Ammonia).

Hydrogen reacts with *carbon* at high temperatures to yield methane. The equilibrium of the reaction is on the methane side at low temperatures, and on the hydrogen and carbon side at high temperatures. The equilibrium constant, using graphite as a basis, is 2×10^5 bar at 150 °C and 9.4×10^{-3} bar at 1000 °C. Equilibria related to amorphous carbon and other values are given in [26], [27]. Carbon monoxide and carbon dioxide can react with hydrogen in the presence of a catalyst. Depending on the reaction conditions, catalyst and CO : H_2 ratio a variety of products can be formed (⟶ Gas Production, see Section Synthesis Gas).

Unsaturated hydrocarbons are converted to saturated or partially saturated hydrocarbons by hydrogenation.

Further reactions of hydrogen include reductions of functional organic groups ($–NO_2$ ⇒ NH_2, –COOH ⇒ CH_2OH, etc). In the petroleum industry (⟶ Oil Refining) hydrogenation and hydrocracking reactions are of importance as well as desulfurization and selective hydrogenation (dienes, monoolefins). For details of reduction and hydrogenation with hydrogen of other compounds see the appropriate keywords.

A great number of *metals* react with hydrogen to form hydrides. Depending on the nature of the hydrogen bond, hydrides are classified into three principal categories: saline, covalent and metallic (see surveys in [20], [21]), (⟶ Hydrides).

The *saline hydrides* or ionic hydrides are formed when the strongly electropositive alkali metals and the alkaline earth metals (calcium, strontium, barium), all usually in the elemental form, react with hydrogen at high temperatures. Salt-like hydrides contain the hydride ion, H^-; they are crystalline, have high heats of formation and high melting points. They are reactive, powerful reducing agents, all of them reacting with water to liberate hydrogen.

Covalent hydrides may be either solid, liquid or gaseous; typical are the hydrides of boron, aluminum, silicon, germanium and tin. Beryllium and magnesium hydride seem to represent a transition between ionic and covalent hydrides. The bond between hydrogen and the atom is of the nonpolar electron-sharing type. Molecular stability often is provided by means of three-centered two-electron bridge bonds (e.g., in diborane, B_2H_6, an electron-deficient type molecule), by hydride anion formation (BH_4^-, AlH_4^-), or formation of polymeric structures [polymeric $(AlH_3)_x$].

Metallic hydrides are formed by the transition metals. Transformation of a pure metal into a hydride occurs through continuous solution of hydrogen in the metal with subsequent abrupt phase transition at defined stoichiometric hydride phases (ZrH_2, PdH, VH, VH_2).

The Hydrogen Bond. Substances containing hydrogen coupled to the most electronegative elements exhibit properties that are best explained by assuming that the hydrogen atom of an H – X bond still has a small but significant affinity for other electronegative atoms although it remains strongly bonded to the original atom. This relatively weak secondary bond is called a hydrogen bond normally depicted by the notation

$$X-H\cdots\cdots Y$$

Hydrogen bonds result in molecular association. NH_3, H_2O, and HF have much higher boiling points and heats of vaporization than the corresponding homologues PH_3, H_2S, and HCl. Carboxylic acids such as acetic or benzoic acids are present as dimers with the configuration

The presence of hydrogen bonds also causes formation of crystalline hydrates such as $NH_3 \cdot H_2O$, $SO_2 \cdot H_2O$ hydrocarbon hydrates (e.g., with natural gas components) as well as the zig-zag structure of the $(HF)_n$ polymer.

The existence of the hydrogen bond can be shown by infrared spectroscopy. When the hydrogen of the X – H group forms a hydrogen bond with the atom Y, the X – H stretching frequency is lowered and the absorption band characteristically broadened. In NMR spectroscopy a proton, which participates in a hydrogen bond, produces a definite paramagnetic shift.

The energies of hydrogen bonds are in the range of 4 – 40 kJ/mol, which is small as compared to 200 – 400 kJ/mol for ordinary bonds. The average bond length is 200 – 300 pm (O – H . . . O in ice 276 pm).

Atomic Hydrogen. Atomic hydrogen is much more reactive than the molecular form. The dissociation reaction

$$H_2 \rightarrow 2\,H;\;\; \Delta H^0 = 432.2\,kJ/mol$$

is highly endothermic. Atomic hydrogen can be produced thermally by supplying sufficient energy, e.g., in electric arcs with a high current density, electrical discharges at low pressures, irradiation with UV light as well as electron bombardment (10 – 20 eV). The hydrogen atom has a short half-life (ca. 0.3 s) and reacts even at room temperature with nonmetallic elements such as halogens, oxygen, sulfur, and phosphor to form the corresponding hydrogen compounds. At room temperature it reduces many oxides to the elements. The heat of recombination of hydrogen molecules from hydrogen atoms leads to very high temperatures (Langmuir flare, 4000 K).

Atomic hydrogen can be absorbed in the metallic structure of some elements of the Group 8 – 10 (Fe, Co, Ni) of the periodic system. The suitability of many catalysts for reactions involving hydrogen is based on the dissociation and solubility of hydrogen in the atomic form.

Hydrogen formed upon dissolution of metals in acids is very reactive at the moment of formation (nascent hydrogen), much more than normal hydrogen. This strong reduction capability is often explained by a shortterm formation of atomic hydrogen. Another explanation is the intermediate formation of a hydride-type compound which is very similar to Grignard compounds (⟶ Magnesium Compounds).

The Hydrogen Ion. The ionization potential of the reaction

$$H(g) \rightarrow H^+(g) + e^-;\;\; \Delta H = 1310\,kJ/mol$$

is 13.595 eV, which is even higher than the first ionization potential of the noble gas xenon.

The hydrogen ion can be formed only in a medium which solvates the protons. The solvation process provides the energy required for bond rupture, the order of magnitude can be seen in the solvation reaction with water:

$$H^+(g) + xH_2O \rightarrow H^+(aq);\;\; \Delta H = 1070\,kJ/mol$$

In aqueous systems H_3O^+ is the form implied by the customary designation hydrogen ion. The structure of the H_3O^+ ion is that of a rather flat triangular pyramid with a HOH bond angle of ca. 110^0, O – H bonds distances of 102 pm and a H – H distance of 172 pm. Normally, it is coordinated with four water molecules not all of which are equivalent, so that the aquated hydrogen ion is best represented as $H_9O_4 \cdot H_2O$ [28]. The lifetime of an individual H_3O^+ ion is exceedingly short, 10^{-13} s, because the protons are rapidly exchanged among the water molecules.

Hydrogen Electrode. In aqueous solutions the hydrogen ion activity is given in terms of the pH value, defined as log 1/[H^+], where [H^+] is the hydrogen ion activity. By definition, the potential of the redox system

$$1/2\,H_2(g) \rightarrow H^+(aq) + e^-$$

is zero (*E* = 0.000 V) at all temperatures, when an inert metallic electrode is immersed in a solution of unit activity (i.e., pH = 0) in equilibrium with hydrogen gas at 100 kPa pressure. The electrode material is a small platinum foil or a wire, coated with finely dispersed platinum black and is placed partly in the solution and partly in the hydrogen atmosphere. This standard hydrogen electrode is the reference electrode of all other oxidation-reduction systems.

For pH measurement the potential difference of a hydrogen electrode to any other suitable reference electrode can be used. The calomel electrode, or half-cell, is usually employed. The pH value is given by

$$pH = \frac{(\Delta\varepsilon - \varepsilon_v)}{0.059} - \frac{1}{2}\log p_{H_2}$$

where: $\Delta \in$ is the potential difference between the hydrogen and the reference electrode (in Volt), $\in_v$ the potential of the reference electrode (in Volt), and p_{H2} the hydrogen partial pressure (in bar) [29], [30].

2.3. Ignition and Detonation Performance

Given sufficient thermal activation (ignition energy), hydrogen reacts more or less violently with oxidizing agents such as oxygen (air), fluorine or chlorine, and N_2O. Depending on conditions, combustion, deflagration or detonation may occur.

Ignition and detonation properties of *hydrogen – air mixtures* are particularly important from the safety aspect (see also Section Safety Aspects). The flammability limits (i.e., the difference between the rich and lean limit concentration) are exeptionally wide for hydrogen. Table 10 shows a comparison of safety-relevant thermo-physical and combustion properties of hydrogen with those of methane, propane

and gasoline [31]. The flammability limits are affected by temperature as shown in Figure 11, so that a preheated mixture has considerably wider limits for coherent flames [32]. An increase in pressures up to 10 kPa has only a small effect. Water vapor has a strongly inhibiting influence on the oxyhydrogen reaction (see ternary diagram, Figure 12). The flammability limits of hydrogen in *pure oxygen* are 4.65 – 93.9 vol % hydrogen, those of deuterium in pure oxygen 5.0 – 95 vol %. Ignition and detonation performance based on ignition range, ignition energy, flame propagation as well as transition from deflagration to detonation, are discussed in detail in Section Safety Aspects.

Table 10. Combustion and explosion properties of hydrogen, methane, propane and gasoline

	Hydrogen	Methane	Propane	Gasoline
Density of gas at standard conditions, kg/m^3 (STP)	0.084	0.65	2.42	4.4 [a]

Hydrogen reacts with chlorine after excitation with radiation, heat or in the presence of catalysts. The ignition and explosion behavior of this reaction is of interest for the chlor-alkali electrolysis, because chlorine is usually liquefied after formation. The residual gas contains hydrogen (among other components) and might reach the ignition or detonation range because of the decreasing chlorine concentration in the gas phase during chlorine liquefaction.

The lower ignition limit of hydrogen-chlorine air mixtures is ca. 4 – 6.5 vol % H_2, the upper ignition limit lies between 73 vol % H_2 (Cl_2 concentration = 0 vol %) and 89 vol % H_2 (air concentration = 0 vol %). The lower detonation limit is between ca. 20 vol % H_2 (Cl_2 concentration = 0) and ca. 25 vol % H_2 (Cl_2 concentration = 30 – 40 vol %). An overview of the ignition and detonation properties of hydrogen – chlorine mixtures, and the influence of oxygen and inert gas is given in [34].

2.4. Isotopes

Hydrogen and deuterium are stable isotopes; tritium emits a low-energy β-radiation (disintegration into ${}^{3}_{2}He$). The half-life is 12.26 a. The natural isotope distribution on earth is 99.985 atom % H and 0.0145 atom % D. Natural tritium occurs in the upper atmosphere and is caused by interaction of cosmic rays, mainly according to:

$$ {}^{14}_{7}N + {}^{1}_{0}n \rightarrow {}^{3}_{1}T + {}^{12}_{6}C $$

Other tritium sources are nuclear reactors, where tritium is formed from lithium or D_2O by a neutron capture mechanism:

$$ {}^{6}_{3}Li + {}^{1}_{0}n \rightarrow {}^{3}_{1}T + {}^{4}_{2}He $$

$$ {}^{2}_{1}D + {}^{1}_{0}n \rightarrow {}^{3}_{1}T $$

Tritium is also formed by fission processes, e.g., in nuclear experiments. Tritium disintegration and varying formation rates lead to changes in the tritium content. It is estimated to be ca. 10^{-13} – 10^{-12} atom % of the total hydrogen [35]. An overview is given in [36] and [37].

Physical Properties. The most important atomic and molecular data of hydrogen, deuterium, tritium and their diatomic combinations are given in Table 1. Further thermodynamic data are tabulated in [38] for deuterium and [39] for tritium. Hydrogen, deuterium, and tritium show nuclear spin isomerism (see Section General Physical Data).

Figure 13 shows the vapor pressures of hydrogen molecules with a different isotopic composition. In [40] the system D_2 – DT – T_2 is described in the range 17 – 22 K. The compounds are totally miscible in the liquid and in the solid state. A 50 : 50 mol % mixture of D_2 – T_2 has a T content of 42 % in the gas phase and of 52 % in the solid phase at 19.7 K.

Figure 13. Vapor pressure of hydrogen isotopes a) H_2; b) HD; c) HT; d) D_2; e) DT; f) T_2

Various chemical and physical processes are used for the enrichment and separation of D_2 or D_2O from the natural isotopic mixture. All chemical processes are based on isotopic exchange reactions, e.g., the dual temperature H_2O – H_2S process, according to

$$ H_2O + HDS \rightleftharpoons HDO + H_2S $$

in the ammonia exchange process

$$NH_3 + HD \rightleftharpoons NH_2D + H_2$$

and variations of this process such as the methylamine hydrogen process from Aecl-Sulzer according to

$$CH_2NH_2 + HD \rightleftharpoons H_2 + CH_3NHD$$

The processes are described in [36] as well as in ⟶ Isotopes, Natural.

On a small scale the electrolysis of enriched H_2O – D_2O is used, because this gives an isotopic separation factor of 7 – 8.

Low-temperature destillation of H_2 – D_2 is an example of the physical separation of the isotopes [41]. The heat generated by the ortho-para conversion must be taken into consideration. Other processes use *pressure swing adsorption* techniques [42]; the various permeation rates of H_2 and D_2 through *metal membranes* (Pd, Ta); or differences in the hydride or deuteride formation with metals [43], (see Section Hydrogen-Energy Conversion Systems).

In general, the *chemical properties* of H, D and T are essentially identical. Small differences exist in the rates and the equilibrium constants of reactions because of the kinetic isotope and equilibrium effects. A greater amount of energy is required for the dissociation of a D – X bond and the activation into the transition state than for the comparable H – X bond (for numerable investigations see [44]). In biological systems substitution of deuterium for hydrogen atom can alter the delicately balanced processes substantially.

Deuterium has excellent properties as a moderator (i.e., a high ratio of neutron deceleration to absorption characteristics). The separation of the hydrogen isotopes is technically important for the production of heavy water (D_2O) as a moderator for nuclear reactors (⟶ Nuclear Technology).

Tritium also is used to mark organic compounds and for dating specimens. A detailed description of tritium and its compounds is found in [45].

[Top of Page]

3. Occurence

Hydrogen is the most abundant element in the universe. 70 – 80 wt % of the observable universe consists of hydrogen, the rest is mostly helium. Especially the younger stars (the novas) inter-stellar dust, and gas clouds contain hydrogen in large amounts. More than 50 wt % of the sun consists of hydrogen.

The neutral hydrogen atom which emits electromagnetic waves with a frequency of 1420 MHz, yields information on the structure of the universe. Large regions of interstellar space are filled with protons, which emit a radio continuum [46], [47].

Of the elements in the earth's crust, hydrogen takes the 9th place with 0.88 wt %. Based on the atomic concentration of 15.4 atom % it is the third most common element after oxygen and silicon. In the free state, hydrogen can be found in some vulcanic gases (up to ca. 30 vol %), in natural gas (from traces up to 40 vol % [48]); small quantities are trapped in some minerals, rocks and meterorites. In the upper atmosphere, the troposphere and the stratosphere, hydrogen is present only in traces of ca. 0.5 ppm (mL/m^3). Because of photolytic water cleavage the hydrogen concentration increases with increasing height. The exosphere (2000 – 20 000 km) contains atomic hydrogen.

Chemically bound hydrogen is present all over the earth: as part of the Earth's water mass (11.2 wt %), as part of organic matter (including fossil substances such as natural gas, oil, and coal). About 10 wt % of the human body consists of hydrogen.

[Top of Page]

4. Production

Hydrocarbons are the main source for the production of hydrogen on an industrial scale. An even larger source, however is water. When hydrogen is used as fuel, water is produced again. Thus, a cycle comparable to the carbon cycle (CO_2 – biomass – CO_2) —but much simpler—is involved, so that water can be regarded as an unlimited source of hydrogen. With the help of an external energy source, hydrogen can be produced from either of these sources alone or from a mixture of both.

Figure 14 shows the production of hydrogen using different sources of energy. The many production routes for hydrogen, however, are by no means of equal economic importance. Most of the hydrogen for industrial uses is produced from natural gas and oil, either as a main product or as a byproduct, a process involving a chemical conversion. A smaller percentage is produced electrolytically or occurs as a byproduct of electrochemical processes. Here the energy applied is in the form of electricity, which itself may be produced using hydroelectric, nuclear or, still predominant, the energy stored in fossil fuels.

Figure 14. Primary energy, raw materials, production methods, paths of production, transformation, and generation of and for hydrogen, adapted from [49]

Thermal, thermochemical, biochemical and photochemical processes have so far not found industrial applications. The preference of producing hydrogen from hydrocarbons is due to the fact that the energy demand using hydrocarbons is much lower than that for electrolysis of water (see Table 11).

Table 11. Theoretical energy consumption for the production of hydrogen from various hydrocarbons, coal and water

	Natural gas as CH_4	LPG as $CH_{2.6}$	Naphtha as $CH_{2.2}$	Heavy oil as $CH_{1.4}$	Coal as $CH_{0.7}$	Water H_2O

kJ/mol	890	2480				
Byproducts	CO_2	CO_2	CO_2	CO_2/S	CO_2/S	O_2
Specific production of byproducts, kmol/kmol H_2	0.25	0.30	0.32	0.37/0.003 – 0.015	0.43/0.002 – 0.01	0.5
Theoretical energy consumption, * kJ/kmol H_2	**41 280**	**37 500**	**38 350**	**50 300**	**57 150**	**242 000**

* Calculated from the heat of formation, oxidizing carbon completely to carbon dioxide (at 298 K and 0.1 MPa) [73], [78].

Considering the strong correlation between energy prices and the prices for hydrocarbons, it is unlikely that the high percentage of the hydrocarbon processes for producing industrial hydrogen will change substantially in the near future. This last statement does not take into consideration environmental pollution by emission of carbon dioxide, sulfur compounds, nitrogen oxides and heat, so that this (environmental) aspect may reverse the situation one day.

4.1. Production from Coal and Hydrocarbons

The yield of hydrogen from hydrocarbons is summarized in Figure 15. Hydrocarbons and coal are characterized by their molar H : C ratio. Chemically pure compounds such as methane and its homologues can be found on line (A) and give maximum hydrogen yield. Raw materials such as hard coal (a), lignite (b) and natural gas (h) give a lower hydrogen yield because they contain inert components (sulfur, nitrogen, oxygen or minerals etc.). Other important sources for the production of hydrogen such as vacuum residue (c), naphtha (d) or hydrogen-rich off-gases (e.g. coke oven gas (j), are also shown in Figure 15.

Figure 15. Hydrogen production from hydrocarbons and coal

A) Maximum theoretical yield from (a) hard coal, (b) bituminous coal, (c) vacuum residue, (d) naphtha, (e) butane, (f) propane, (g) ethane, (h) natural gas, (i) methane, (j) coke oven gas

B) Commercial production by steam-reforming, including fuel, no credit for export steamLower curve: small plants, ca. 500 m^3 (STP)/hUpper curve: large plants

C) Commercial production by partial oxidationlarge plants only

Upper curve: without oxygen production

The yields actually achieved in industrial hydrogen production are quite different from the maximum possible theoretical yields. This, however, is not due to a low degree of conversion but to the fact, that the energy needed to produce hydrogen is usually supplied by the raw material itself. Technical and economic aspects of the production are dealt with in this chapter. For the latter not only the yield but also the prices of the feedstock and the investment costs for the plant are important. Because of the fact that (1) there are only small differences between the cost of hydrocarbons on the basis of heating value, (2) the investment costs for the production of hydrogen from light hydrocarbons are lower, and (3) yields from light hydrocarbons are higher, as shown in Figure 15, hydrogen is produced preferably from light hydrocarbons, if available.

4.1.1. *Coke Oven Gas (see also* ⟶ Coal Pyrolysis*)*

Coke oven gas (COG) was formerly a major source of hydrogen. Coke oven gas provided, in conjunction with water gas, almost all of the hydrogen for ammonia synthesis and for coal liquefaction (⟶ Coal Liquefaction) in the first half of this century. While the demand for hydrogen has risen sharply since 1950, the production of coke has been reduced. New production techniques for steel as well as reduced steel production in most industrialized countries have led to a decreasing market for coke and COG. Producing iron by direct reduction of iron oxide pellets with synthesis gas, for example, requires no coke at all. Nevertheless COG is, where available, an important and convenient source of hydrogen, but on the whole, production from coke oven gas has now been replaced by more effective hydrocarbon-based processes and by coal gasification.

Modern coke oven plants produce ca. 350 m^3 (STP) of coke oven gas per tonne of coal (15.6 mol/kg). 45 % of the raw COG produced is utilized to fire the coke oven batteries and supply other energy requirements of the coke oven plant. The rest can be used as a source of hydrogen or exported as a fuel gas. It can be expected that further developments and better heat management within the coke oven plant will raise the amount of excess gas up to 70 % of the total gas produced [50].

Raw Gas Treatment. Coke oven gas leaves the coke oven batteries at 750 – 850 °C and approximately atmospheric pressure. The main impurities which have to be eliminated are tar, several heavy to medium oil fractions with a high aromatic content, hydrogen cyanide, ammonia, organic and inorganic sulfur compounds, naphthalene, nitrogen oxides and water. The concentrations of the impurities vary with the kind of coal and the type and duration of the coking process. Several proprietary techniques for cleaning of raw COG are available [51], [52]. Typical cleaning steps are:

1. Quench cooling to ambient temperature (15 – 30 °C) and separation of the oil and naphthalene fractions,
2. First raw gas compression,
3. Absorption of hydrogen cyanide, ammonia, and sulfur compounds,
4. Second raw gas compression

Pretreated COG contains 50 – 60 % hydrogen (see Table 12).

Table 12. Range of composition for precleaned coke oven gases and production of hydrogen from typical gas by pressure swing adsorption

Components	Range of composition, vol %	Typical composition, vol %	Hydrogen product, vol %	Fuel gas, vol %
H_2	50 – 64	57	99.9*	22
N_2	3 – 12	3	0.09	5.5
CO	4 – 8	6.5	<10 ppm	12
CO_2	1 – 5	3	< 1 ppm	5.5

Typical flows with pressure swing adsorption, m^3 (STP)/h		100	45	55

* Possible up to 99.999 %.

Separation of Hydrogen from Pretreated COG. The separation of hydrogen from pretreated COG has been accomplished in two different ways.

Low-Temperature Condensation. Conventionally, hydrogen is separated by a low-temperature condensation process. Condensation of methane, ethylene and other compounds with a higher boiling point is carried out in regenerators (large vessels filled with ceramic materials) at elevated pressures (0.5 – 1 MPa) and low temperatures (60 – 70 K).

The hydrogen purity attainable is 96.5 %. Utilizing the low temperatures, hydrogen can be further cleaned in a liquid nitrogen scrubber (see Section Low-Temperature Absorption Processes), where the residual methane, carbon monoxide and oxygen content can be reduced down to low levels. In the nitrogen scrubber, the gas can be conditioned for ammonia synthesis gas production (25 % N_2, 75 % H_2).

By fractionating the primary condensate from the regenerators ethane, ethylene, propane, and fuel gas can be obtained as byproducts along with hydrogen or ammonia synthesis gas.

Plants with capacities up to 3×10^5 m^3 (STP)/h have been built using this type of technology.

Pressure Swing Adsorption. Pure hydrogen can be recovered at much lower investment costs in modern pressure-swing adsorption (PSA) plants (⟶ Adsorption – Regeneration by Pressure Swing). A first industrial-scale plant with 10 000 m^3 (STP)/h capacity was put into operation in the German Ruhrgebiet in 1982. Figure 16 shows the principal steps of the plant.

Figure 16. Hydrogen production from coke oven gas by pressure swing adsorption (Linde, Federal Republic of Germany)

a) Raw gas compressor; b) Cooler; c) Preadsorption (regeneration not shown); d) Pressure swing adsorption; e) Oxygen removal; f) Water removal; g) Rest gas equalizer; h) Fuel gas compressor

After compression, higher hydrocarbons and sulfur compounds are separated from the raw gas by a preadsorption stage. Separation of hydrogen from the other gas components occurs in an adsorption process with four or more beds (see Section Adsorption Processes).

Special precautions must be taken to avoid accumulation of oxygen on the adsorbent. Part of the oxygen remains in the product gas and is converted to water in a special reactor (see Section Selective Oxidation for Deoxo reaction). Hydrogen is then dried in another adsorption process yielding a purity >99.9 %, before it is delivered to a hydrogen pipeline system (see Chap. Handling of Hydrogen).

About 80 % of the hydrogen is recovered by this process. Thus, depending on the initial composition, the gas volume is reduced by 40 – 50 % on producing pure hydrogen. However, the residual gas, which is usually used for firing the coke oven batteries or otherwise as a fuel gas, has a lower heating value (LHV) of ca. 587 kJ/kmol so that recovery of the valuable hydrogen product stream leads only to a 20 – 30 % drop in the total heat content of the remaining fuel gas (see Table 12).

Proposed Technology for Production of Hydrogen from COG by Chemical Processes. A higher hydrogen yield could be obtained, if the hydrocarbons in the raw or pretreated COG were converted to hydrogen.

Catalytic processes for this purpose are *steam-reforming* and *autothermic* processes (see Section Catalytic Reforming of Hydrocarbons). Both processes run best when the sulfur content is low and unsaturated and cyclic hydrocarbons are absent. This requires multi-stage precleaning processes, which are technically feasible and often used for other applications (⟶ Gas Production). For COG, however, they have not yet been commercially applied so far though they have been frequently proposed [53], [54].

Partial oxidation of COG (see Section Gasification of Coal and Hydrocarbons) has also been proposed [52]. But, because of difficulties with the low initial pressure (approx. atmospheric) and the periodical changes in amount and composition of COG, no commercial application has been reported.

The above refers to COG from hard coal only. Similar aspects apply when gas from *coking operations* in refineries (see Section Refinery Processes) or from modern *pyrolysis* processes of hard coal, lignite, organic materials (straw, refuse, etc.) is considered as a source of hydrogen.

4.1.2. *Gasification of Coal and Hydrocarbons*

4.1.2.1. *Coal Gasification*

For the production of hydrogen or hydrogen-rich gas streams coal gasification is usually performed with oxygen (purity > 95 %) at high temperature and elevated pressure. Coal gasification is described in detail elsewhere (⟶ Gas Production). Here, only aspects relevant to the production of hydrogen and hydrogen-rich gases are dealt with.

Coal gasification on an industrial scale produces:

1. Synthesis gases, rich in carbon monoxide and hydrogen, e.g., gas for Fischer-Tropsch synthesis of gasoline at SASOL, South Africa (⟶ Coal Liquefaction), [55];
2. Synthesis gas for the production of acetic anhydride at Tennessee Eastman, United States [56];
3. Ammonia synthesis gas: 3 H_2 + N_2, e.g., Modderfontein, South Africa [57];
4. Substitute natural gas >90 % CH_4, e.g., North Dakota, United States [58];
5. Medium- and low-Btu fuel gas for combined-cycle processes [59] consisting of hydrogen, carbon monoxide, methane, carbon dioxide. The gas may also contain considerable amounts of inerts (nitrogen, argon), if gasification is performed with air.
6. Pure hydrogen (hydrogen content > 95 %) from a side stream of a synthesis gas unit [60].

All coal gasification processes can be used to manufacture hydrogen. The highest yield in the primary gasification step, however, is achieved, if pulverized coal is gasified with oxygen at high temperatures. This is done in the entrained-bed gasification reactor, commercialized especially in the Koppers – Totzek and the Texaco process.

The most important process steps are shown in Figure 17 for the Texaco coal gasification process.

Figure 17. Texaco coal gasification process; direct quench mode of operation

a) Coal grinding mill, b) Slurry tank; c) Slurry pump; d) Texaco gasifier; e) Quench chamber; f) Lockhopper; g) Particulate scrubber; h) Clarifier; i) Slag separator; j) Slag sump

Gasification temperatures > 1300 °C result in a synthesis gas which contains only minor amounts of methane and other hydrocarbons. The chemical equilibrium at these temperatures leads to a gas containing mainly hydrogen and carbon monoxide (see Table 13). The latter can be shift converted to hydrogen (see below).

Table 13. Hydrogen production by coal gasification. Effect of gasification pressure, temperature and operation mode

	Low temperature gasification	Medium temperature gasification	High temperature gasification

* waf = water and ash free.

Gasification pressure affects the hydrogen yield and the economics of the process. Whereas the yield of hydrogen is slightly reduced, the economics are improved at high pressure because hydrogen is usually utilized at higher pressure. Modern gasification processes, therefore, are operated at least at 2 MPa. The negative effect on the hydrogen yield can be offset by a slight increase in temperature.

Table 13 shows the operating conditions of several commercial gasification processes. Since different coals have been gasified, the hydrogen yields cannot be compared directly. However, the influence of gasification temperature on hydrogen yield and the formation of byproducts can be clearly seen.

Principally, all types of coal can be gasified to produce hydrogen, although certain constraints associated with the gasification process or the characteristics of the coal have to be considered. The gasification of *petroleum coke* in a fluidized bed gasifier has been proposed [61] and the gasification of coke from *tar sands* has been successfully tested in an entrained bed gasifier [62].

Gasification of other solid fuels such as peat, wood, refuse, or sludge from wastewater treatment plants leads to a low-Btu gas, which is less suitable for the production of hydrogen. Because of the high

moisture and oxygen content of the raw material, these gases are generally used on the plant site for heat or electricity production. In Finland one plant is in operation since 1988 which produces ammonia synthesis gas from peat, employing a high temperature Winkler gasifier (⟶ Gas Production) [63].

Research and Development. Commercial conditions, namely the low crude oil prices in the 1980s, have prevented further development of new coal gasification processes developed in the 1970s from bench-scale experiments to commercial-scale processes. Instead research has aimed at making the established processes more reliable. Further progress has been made in improving the purification steps from the raw synthesis gas to pure hydrogen (see Chap. Purification of Hydrogen).

4.1.2.2. *Gasification of Liquid and Gaseous Hydrocarbons*

Partial oxidation of hydrocarbons in general is described in detail elsewhere (⟶ Gas Production – Partial Oxidation of Hydrocarbons). For the production of hydrogen, the Texaco and the Shell partial oxidation (PO) processes are applied commercially [64-67].

The principal steps of an oil gasification process (Texaco process) are similar to the coal gasification depicted in Figure 17. The Shell process differs in details such as the burner construction, the reactor cooling, the waste heat boiler and the soot recycle. Some more details of both processes are given below:

Feedstock	Problems
High boiling point fractions	Cracking and carbon formation on heating, high pressure drops at high viscosity
Solid residues	Slurrying hydrophobic residues, high demands on the burner
High metal content	Corrosion and metal deposition in down-stream equipment
Ash and slag content	Mechanical equipment for solid removal, melting point of the ash, eutectic formation with brick work, wear by erosion
Treatment of carbon deposits	No recycle: carbon loss, disposal problems Recycle: metal content build-up
Heat recovery	Quench: reliability, direct steam production for shift conversion applied with: H_2 production
	Waste-heat boiler: high steam production rate; applied with: synthesis gas production

Heavy residues from petrochemical processes are the preferred feedstocks for the production of hydrogen and carbon monoxide-rich gases. Oil fractions with high sulfur and/or high heavy metal contents are difficult to handle in upgrading processes such as hydrogenation or coking. For environmental reasons they should not be used as fuels. In principle, hydrogen can be produced by PO processes from all hydrocarbons. The production, however, is only economically viable if heavy residues are utilized. (see Section Economic Aspects for an economic comparison of hydrogen-producing processes).

Gaseous hydrocarbons are also occasionally converted to hydrogen and carbon monoxide in PO processes. This is done, if the gases cannot be processed by catalytic steam reforming (see Section Catalytic Reforming of Hydrocarbons) because of high concentrations of certain impurities such as olefins and H_2S or if the process must handle various feedstocks from natural gas up to fuel oils. Another incentive to use PO for the conversion of gaseous fuel is the possibility to obtain synthesis gas with a high carbon monoxide content.

The overall reactions during partial oxidation are as follows (heat of reaction see Table 14):

Oxidation reactions

$$C_mH_nS_o + m/2\,O_2 \rightarrow mCO + (n/2 - o)H_2 + oH_2S\,(\text{exothermic}) \quad (1)$$

$$2\,C + O_2 \rightarrow 2\,CO(\text{exothermic}) \quad (2)$$

Crack reaction

$$C_mH_nS_o \rightarrow (n/4 - o/2)\,CH_4 + (m - n/4 + o/2)C + oH_2S\,(\text{endothermic}) \quad (3)$$

Water gas reaction

$$C + H_2O \rightarrow CO + H_2\,(\text{endothermic}) \quad (4)$$

Shift reaction

$$CO + H_2O \rightarrow H_2 + CO_2\,(\text{exothermic}) \quad (5)$$

Methane reforming

$$CH_4 + H_2O \rightarrow \leftarrow CO + 3\,H_2 (\text{endothermic}) \quad (6)$$

Table 14. Equations and reaction enthalpies for the most frequent reactions occurring during catalytic steam reforming and their technical conditions [78]

The reactions of the hydrocarbon feedstock with substoichiometric amounts of pure oxygen (oxygen content > 95 %) follow Equation (1). Other reactions, which take place simultaneously or immediately following, are the water gas reaction (Eq. 4), the CO shift (Eq. 5) and the methane formation or decomposition reaction (Eq. 6).

The reactions take place primarily in the flame and in the empty brick-lined reactor. The residence time is usually <5 s, the temperature 1250 – 1500 °C. Pressure is often adjusted to accomodate subsequent processes, 3 – 12 MPa being the usual range.

The subsequent formation of hydrogen by the water – gas shift reaction (Eq. 5, see also Section Catalytic Gas Purification), is of equal importance for hydrogen production as is the immediate formation of hydrogen (Eq. 1). Carbon monoxide is thereby shifted to hydrogen to the highest degree possible. The shift reaction occurs simultaneously to the oxidation-gasification reactions at temperatures > 1200 °C without the presence of catalysts. Higher hydrogen yields, however, can be achieved by attaining equilibrium at 200 – 500 °C in the presence of steam and suitable catalysts.

Two process routes have been applied to perform the cooling down, gas purification and shift reaction:

1. The classical sequence of the three aforementioned process steps calls for a two-stage physical scrubbing process (e.g., the Rectisol wash, see Section Scrubbing Processes). The process gas from the partial oxidation reactor is cooled in a waste-heat boiler thus producing high pressure steam. Soot and ash particles, as well as water-soluble components, are removed with a water quench at temperatures between 300 °C and ambient. Hydrogen sulfide is removed (e.g., at – 50 °C) in the first stage of a Rectisol absorption unit. The synthesis gas is then heated again to 300 °C and steam is added. The shift reaction occurs in a series of adiabatic reactors with intermediate cooling and decreasing inlet temperatures at each stage. After subsequent carbon dioxide removal in the second stage of the absorber the carbon monoxide content can be as low as 0.5 vol %. The catalyst, especially the one used at the lowest temperature, is extermely susceptible to sulfur poisoning (see Section Adsorption Processes).
2. Since sulfur-tolerant shift catalysts have been developed (see Section Adsorption Processes), an alternative process has become possible. Here the high water content required in the gas for the CO-shift reaction is achieved by direct quenching of water into the raw gas. The shift reaction takes place in a series of adiabatic reactors without prior removal of sulfur. It has been proposed to replace them by one temperature-controlled, quasi-isothermic reactor [68]. The sulfur compounds hydrogen sulfide, carbonyl sulfide, and carbon dioxide are removed in a single stage Rectisol wash, which in its regeneration section can produce two separate fractions, namely a carbon dioxide and a hydrogen sulfide – carbon dioxide mixture. The CO content of the purified gas is <0.5 vol %.

4.1.2.3. *Examples of Industrial Scale Hydrogen Production (by Partial Oxidation of Hydrocarbons)*

Production of Hydrogen-Rich Ammonia Synthesis Gas. One example is the production of hydrogen-rich ammonia synthesis gas by partial oxidation of high-sulfur-content vacuum residue (⟶ Ammonia).

Starting from 44 t/h vacuum residue with a sulfur content of up to 4.5 wt %, 116 000 m^3 (STP)/h of 96 vol % pure hydrogen are generated. Hydrogen is further purified using a liquid nitrogen scrubber (⟶ Gas Production – Liquid Nitrogen Wash Process), whereby 148 900 m^3 (STP)/h of ammonia synthesis gas with a composition H_2 = 75 mol % and N_2 = 25 mol %, is obtained. 56.25 t/h of ammonia can be produced from this synthesis gas.

Hydrogen from Residues of Upgrading Operations in Refineries [69], [70]. After optimization of many technical, environmental and economic parameters the process sequence in Figure 18 consists of the following steps:

1) *Air Separation*	Molecular sieve unit (because of the high air pollution at the site)
	External compression of oxygen to 7.5 MPa
2) *Gasification*	Texaco combined reactor in two parallel trains (special arrangements to cope with high ash concentrations in the feedstock)
3) *Soot extraction*	100 % soot recycling, using the Texaco naphtha soot extraction system No special extraction oil required
	Vertical decanter
4) *Carbon monoxide converter*	3 beds with cobalt – molybdenum sulfide catalyst with a residual carbon monoxide concentration of 0.5 vol %. Waste-heat recovery for steam generation and other uses within the plant
5) *Sour gas absorber*	Single-stage selective Rectisol absorber, two parallel absorbing columns for converted and carbon monoxide-rich feed gas
	Purified streams of hydrogen, carbon monoxide, methanol synthesis gas and Claus fraction containing 70 % hydrogen sulfide
6) *Methanation*	Standard version with nickel catalyst and integrated zinc oxide bed.
7) *Carbon monoxide cold-box*	Single column apparatus with internal carbon monoxide recycle (cold-box = containment for low-temperature process)

Figure 18. Gasification of refinery residue for the production of hydrogen, methanol synthesis gas, and carbon monoxide (Linde, Federal Republic of Germany)

4.1.3. *Catalytic Reforming of Hydrocarbons*

A comprehensive treatment of catalytic reforming is given elsewhere (see ⟶ Gas Production – Steam Reforming of Natural Gas and Other Hydrocarbons). Here a brief outline of the most important industrial routes for hydrogen production is given.

4.1.3.1. *Feedstocks*

Hydrocarbons react with steam in an endothermic reaction to form carbon monoxide and hydrogen (Eq. 7, Table 14). The most important feedstock for the catalytic steam reforming process is natural gas. Other feedstocks are associated gas, propane, butane, liquefied petroleum gas and some naphtha fractions. The choice is usually made on the availability and the price of the raw material. Preference is given to lighter feedstock, if the price on a heating value basis is comparable. The reason for this is the better operability of plants using lighter feedstocks as well as the easier pretreatment operations, and thus the lower investment costs for comparable plants.

The chemical process is described by

$$C_nH_m + nH_2O \rightleftharpoons nCO + (n + m/2)H_2 \tag{25}$$

The shift reaction, where carbon monoxide, formed according to (25), reacts with excess water, occurs concurrently to this reaction. Additional hydrogen is formed by this exothermic process:

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \tag{14}$$

Standard enthalpies of some important reactions occurring during steam reforming are given in Table 14. The heat of reaction of the overall endothermic process is provided by indirect heating. In *autothermal reactors* (e.g., secondary reformers) the oxidation reaction (see Table 14) supplies the necessary energy. This reaction takes place simultaneously or in advance of the reforming reaction.

4.1.3.2. *Tubular Reformer*

The equilibrium of the hydrocarbon steam reaction (7) and the water-gas shift reaction (14) dictates the conditions that must be met to achieve maximum hydrogen yields:

high temperature at the end of the reactor
high excess of steam
low pressure

These conditions can be realized best, if the endothermic reforming reaction occurs in a fired tubular reactor at high temperature (800 – 900 °C) and low pressure. The process pressure varies between 1.5 and 3.0 MPa. The exact choice of the process conditions depends on reaction kinetics, mechanical and economical terms.

The amount of steam added to the hydrocarbon feedstock is quantified by the molar steam-to-carbon ratio (S/C = ratio of S moles of H_2O to C moles of carbon contained in the hydrocarbon feedstock. If present, carbon monoxide and sometimes also carbon dioxide, is calculated with the C moles). The S/C ratio has values from 2.5 to 6, depending on the feedstock and subject to process optimization considerations. The principals of the optimization of a steam reformer plant for the production of hydrogen are discussed in more detail in Section Steam Reforming Plant.

The next step is the shift reaction at ca. 340 – 450 °C (high-temperature shift). In certain cases this is followed by a second shift reaction at 200 – 250 °C (low-temperature shift).

Catalyst. In commercial plants steam reforming and the concurrent shift reaction are catalyzed by supported nickel catalysts. The catalyst contains 15 – 25 wt % nickel oxide on a mineral carrier. Carrier materials are α-alumina, aluminosilicates, cement, and magnesia. Before start-up, nickel oxide must be reduced to metallic nickel. This is done preferably with hydrogen but also with natural gas or even with the feedgas itself.

With certain types of catalyst uranium oxide and chromium oxide are used as a promoter. This is reported to give a higher resistance to catalyst poisoning by sulfur components and a lower tendency to form carbon deposits (according to Eq. 21 in Table 14). For special applications such as low-temperature reforming, noble metal catalysts have been developed [71]. They have not been used commercially so far.

For the feedstocks *LPG* and *naphtha*, nickel catalysts with alkaline carriers [72], [73] or alkaline-free catalysts with magnesium oxide as additive [74] can be used. Both types of catalyst are less active than the conventional nickel catalyst. Therefore, a less rapid decomposition of the hydrocarbons is achieved. At the same time, the reaction of water with any carbon formed (Eq. 4) is catalyzed. Catalysts with alkaline carriers are mostly used for the upper part of the reactor tube only. The second part of the reactor is filled with more active nickel catalyst. Whereas the first catalyst gradually decomposes the higher hydrocarbons, the active catalyst is more suitable for the methane-rich fractions formed in the upper part. The aforementioned combination of catalyst can also be employed with natural gas feedstock, thereby offering the opportunity to switch to LPG or naphtha in case of natural gas shortages.

Required properties of the catalyst carriers are high specific area, low pressure drop and high mechanical resistance at temperatures up to 1000 °C. The catalysts are usually in the form of rings (e.g., outer diameter 16 mm, height 16 mm, inner diameter 8 mm). Other forms, such as saddles, stars, and spoked wheels are also commercially available.

The main catalyst poison in steam reforming plants is sulfur, which is present in most feedstocks. Concentrations as low as 0.1 ppm form a deactivating layer on the catalyst [74]. To some extent activity loss of a poisoned catalyst can be offset by raising the reaction temperature. This helps to reconvert the inactive nickel sulfide to active nickel sites.

Worse than small constant sulfur concentrations are sulfur peaks in the feedstock. They lead to permanent deactivation of the catalyst and to mechanical problems because of carbon deposits.

Other catalyst poisons are chlorine and other halogen compounds as well as heavy metals, especially lead, arsenic, and vanadium.

Nickel-free catalysts have been proposed for feedstocks heavier than naphtha [75], [76]. These catalysts consist mostly of strontium, aluminum and calcium oxides. They seem to be satisfactorily resistant to coking and work with high-sulfur feedstocks. However, with these catalysts even at reaction temperatures as high as 1000 °C the methane concentration in the exit gas is so high, that a secondary reformer has to be installed [77].

Equilibrium Conditions and Kinetics. The reactions in commercial reformers lead to a product composition which is usually very close to the equilibrium of the shift reaction (Eq. 14 in Table 14) and of the methane reforming reaction (Eq. 7) for design purposes. The resulting gas composition corresponds to an equilibrium temperature, which is usually only 5 – 20 K below the measured actual outlet temperature.

Higher hydrocarbons than methane are not usually found in the outlet products of a steam reformer. The equilibrium composition can be calculated from equilibrium data given in [73] or [78] as a function of the temperature, pressure and S/C ratio. For the dependence of the equilibrium composition on pressure and temperature at one (undisclosed) S/C ratio see ⟶ Gas Production.

A review of the many aspects of intrinsic kinetics of methane steam reforming is presented [79]. For most practical conditions, ranges of S/C and pressures, first-order kinetics can be employed for methane reforming. For low conversions of methane, which is not typical for industrial use, the concurrent carbon monoxide shift reaction deviates from equilibrium.

For the design of the reforming reactor not only the reaction kinetics within the reformer tube are important, but also the pattern of heat input required for the endothermic hydrocarbon decomposition reactions.

Heat distribution in conventional reformers is influenced (1) by the geometry of burner arrangements, (2) the pitch of the tubes, (3) the type and length of the flame, (4) the radiation of the flames, flue

gases and refractory walls, (5) size, shape and thickness of the tubes, (6) materials, and (7) whether the tube surfaces are machined. The calculation procedure for a standard type of hydrogen steam reformer is indicated in Figure 19.

Figure 19. Tube wall temperature and heat flux in a reformer tube

A) Outer tube wall temperature vs. heat flux profile divided into, e.g., eight reformer sections

B) Hatched area: inclined to the right = heat requirements of the reaction; inclined to the left = heat provided by firing

Iteration for illustration purposes not completed

The radiation conditions in the fire box depend on the temperature of the flue gas, the reformer tubes and the refractory walls, as well as their emissivities. A zonal computer program calculates the interaction among these three factors for the desired heat duty at a given tube skin temperature and results in the firing requirements. The effects of combustion, air or fuel preheat are also considered in this calculation.

The given tube wall temperature is shown in Figure 19 A. The heat duty on the fire box side is shown for eight reformer section zones as one of the lines in Figure 19 B. The program which calculates the composition inside the reformer tube allows the heat requirements per length of tube to be calculated at the same time. This heat is supplied through the reformer tube wall and the given tube wall temperature determines the heat transferred to the inside of the tube. This is shown by the second line in the section zones of Figure 19 B. The aim is thus to find a tube skin temperature profile which will supply the heat to the process as required, or, in other words, to match the heat flux profiles. When this is accomplished, the temperature profile along the tube and the firing rate have been determined. The former is important for the mechanical design of the tube, the latter for the utility consumption.

Other factors, such as heat losses, flame lengths, staged burning, flue gas recirculation, position of the flue gas outlet duct, circumferential and other tube temperature asymmetries, also play a role. Therefore it is essential that results be corroborated by field data and the programs adjusted accordingly to reflect the influence of the above mentioned factors.

The behavior of the radiant section can thus be predicted by the results of these calculations with sufficient accuracy. Literature has been published in this field [80-82]. However, some problems in heat and mass transfer, influence of pressure and the decomposition of higher hydrocarbons are still not completely resolved.

The utilization of the flue gas leaving the reformer is also of prime importance. An exact prediction of the temperature of the flue gas leaving the radiant zone (i.e., bridgewall temperature) is essential because it affects the firing duty (i.e. the amount of heat introduced to the reformer by firing), and thus overall performance of the reformer.

Numerous variations in the order of the heat exachanger coils are possible. Normally the excess heat in the flue gas is utilized to produce export steam. Whatever arrangement chosen, the overall thermal efficiency of reformer and convection zone can normally be expected to be ca. 92 %.

Carbon Deposits. Formation of carbon deposits occurs predominantly because of the decomposition of methane according to Equation (21) in Table 14.

$$CH_4 \rightarrow C + 2\,H_2$$

Other reactions leading to soot formation or carbon-coke deposits are cracking of higher hydrocarbons, especially aromatic compounds, and of olefins.

Another reaction leading to carbon deposition, the Boudouard reaction (22) in Table 14

$$2\,CO \rightarrow CO_2 + C$$

is favored by low temperature and high pressure typically found at the inlet portion of radiant tubes in a steam reformer.

Theoretically at least, carbon laydown can be predicted from the equilibria of Equations (21) and (22) if other carbon monoxide forming reactions such as the steam reforming (4) and the shift reaction (14), are also taken into account (see Table 14).

Since the early investigations of DENT [83] much has been published on the kinetics and conditions of carbon laydown on commercial and experimental catalysts in plants and in the laboratory [84-86]. As a result, several factors influencing soot formation in commercial steam reforming processes have been identified:

Choice of Catalyst. Acid sites on the catalyst and its support, e.g., nickel on silica, catalyze carbon formation. Alkaline supports and a spinel structure of the catalyst permit operation close to the soot limits of equilibrium conditions.

Feedstock Selection and Pretreatment. Olefins and aromatics lead to carbon deposits and catalyst deactivation even in regions which are carbon-free according to equilibrium conditions. Therefore, if the

presence of these compounds cannot be avoided, a recycle of product hydrogen is often used to hydrogenate the unsaturated hydrocarbons. The hydrogen recycle ratio depends on the amount of unsaturated hydrocarbons expected and will often be ca. 3 – 5 mol % of the carbon content of the feedstock. Hydrogenation is usually performed simultaneously to the hydrogenation of sulfur containing compounds and the same type of catalyst (a sulfided cobalt or molybdenum catalyst) can be employed.

Kinetic Effects. High space velocities in critical regions also help to avoid soot formation.

Steam : Carbon (S/C) Ratio. Proper choice of the S/C ratio in steam reforming is imporant. Carbon formation is avoided if high S/C ratios are chosen because the equilibrium of the feed gas is shifted from the carbon regions. The S/C ratio also influences the hydrogen : carbon monoxide ratio of the product gas. This is important, if synthesis gas, not hydrogen, is to be produced. The shift reaction, which follows the reforming stage in hydrogen production plants and in many other applications, is also influenced by the S/C ratio. A high S/C ratio favors hydrogen production. At low S/C ratios, the danger of hydrocarbon formation exists with subsequent carbon deposits in the high-temperature shift reactor. In the worst case reduction of the iron oxide catalyst may even occur.

Finally, economic evaluations indicate that the optimum S/C ratio tends to be low. Figure 20 shows that the feedstock consumption is slightly less at low S/C ratios. Because investment cost also declines with smaller gas flows, lower values of S/C are thus favored, although the aforementioned restrictions must be taken into account.

Figure 20. Consumption of natural gas in a modern hydrogen plant with PSA unit as a function of steam – carbon ratio

a) Total consumption of natural gas; b) Portion of natural gas used as process gas; c) Portion of natural gas used as fuel gas in addition to PSA off-gas [89]

Common values for natural gas operation are S : C 2.5 – 3, and for LPG and naphtha feedstocks S : C 3 – 5. If the desired product is not hydrogen, but carbon monoxide, the S/C ratio should be substantially lower.

Reformer Types. The aim of a reformer design for the production of hydrogen is to obtain a maximum temperature at the exit of the reformer tube and thus the maximum possible degree of reforming, using a minimum amount of fuel.

The fuel utilization is optimized, if the heat delivered to each section of the reformer tube corresponds to the heat requirements of the reaction in the tube. Various types of furnace and the geometry of the tubes and the burners in the furnace are shown in Figure 21 [87], [88].

Figure 21. Types of steam reformer for hydrogen production; furnace and convection zone configurations

Cylindrical Furnaces: A) Small plants, pilot plants; B) Standard configuration; C) Tube/burner configuration for plants with higher capacity (up to 5 000 m^3 (STP)/h = 60 mol/s H_2); Process gas and flames (flue gas) usually cocurrent

Box Furnaces: D) Standard configuration; E) Bottom fired reformer; F) Side fired reformer; G) Terrace wall reformer; H) Combined configuration;

Convection Zone: I) Standard configuration, horizontal at grade; usually cocurrent flow of process gas and flames; J) Vertical configuration, downflow; K) Vertical configuration, upflow; L) Asymmetrical configuration; M) Central configuration;

a) Catalyst filled reformer tube; b) Burner; c) Radiation zone; d) Convection section; e) Fluegas duct; f) Inlet gas distribution system; g) Outlet gas tube (pig tail); h) Collector; i) Flue gas blower; j) Stack

For small reformer plants with a hydrogen capacity of up to 1000 m^3 (STP)/h (12.5 mol/s) cylindrical furnaces are often used. These furnaces require the least expenditure with regard to steel construction and insulation materials and can be prefabricated in the workshop. The plant size is then limited by the maximum transport dimensions.

Figure 21 C shows an arrangement, which accomodates a large number of tubes and allows a hydrogen production of up to 5000 m^3 (STP)/h (60 mol/s). Because of the varying distances of the tubes to wall and burner (see A and B) and because of the varying circumferential heat flux of each tube (C) an even heat flux distribution cannot be attained. This leads to designs with lower overall heat flux and shorter tube lengths for this type of cylindrical furnace.

For larger hydrogen plants box furnaces are well-proven. Often they can be prefabricated, so that a certain degree of preassembly is possible. The various types of box furnaces mainly differ in the arrangement of the burners. For hydrogen plants the usual configuration is the *top-fired* furnace (D), but *bottom-fired* (E), *sidewall-fired* (F) and *combined types* (G, H) are also in use. The box furnace allows a more even heat load distribution to each tube. The heat flux can therefore be increased.

Because the radiation is evenly distributed around the tube, the mechanical stress is minimized and larger tube diameters (up to 0.18 m outer diameter) can be used. The total number of tubes per

quantity of hydrogen produced can thus be decreased. This reduces furnace volume, piping and the number of burners.

In almost all designs the process gas flows through the tubes from the top to the bottom. The hot outlet gas is usually gathered in a manifold system, which may or may not be lined, and led to the process gas boiler. This equipment is best placed at ground level. Three different arrangements are possible for the combination of process gas – flue gas flow.

Most modern reformers are *top-fired reformers* with cocurrent flow. Figure 22 A shows the temperature profile of the outer tube wall and the gas temperature in the tube interior. The high temperature attained rapidly at the beginning of the tube allows a high reaction rate over a large portion of the tube.

Figure 22. Temperature profiles in different steam reformer designs

A) Cocurrent flow; B) Sidewall-fired; C) Countercurrent flow

The upper curve shows the approximate flue gas temperature, the lower curve the temperature of the process gas, with an adjusted inlet temperature of 550 °C and exit temperature of 800 °C. The curve between shows the skin temperature of the tube wall, important for the mechanical design of the reformer tubes

Sidewall-fired furnaces exhibit a very even flue gas temperature profile and allow a certain amount of freedom to adjust the tube wall temperature (see Figure 22 B).

The flue gas exit temperature with a *countercurrent* system is particularly low (see Figure 22 C), which indicates that a large fraction of the heat content of the flue gas has been utilized. This type is used preferentially whenever a furnace with the convection zone at the top, using natural draft, and with a low degree of further utilization of the heat content of the flue gas is envisaged.

Further critical items of steam reformers are:

1. The support of the tubes to minimize the load on the distribution system and to avoid bowing of the tubes.
2. The preheated gas mixture (ca. 500 °C) enters the reformer via the inlet distribution system. The distribution system must be designed to take up the vertical expansion of the reformer tubes (for example, a 14 m tube may expand by as much as 0.25 m under operating conditions).
3. The horizontal thermal expansion of the outlet collector must be compensated for by the connecting pipework, the so-called pigtails.
4. Equal gas distribution over the tubes is attained by proper hydraulic design of the inlet and outlet collectors coupled with uniform loading of the catalyst in the reformer tubes.
5. The ratio of tubes : burners in large top-fired reformers is ca. 4. Smaller numbers of burners have the disadvantage of uneven heat distribution to the tubes but the advantage of lower investments because of the reduction in piping and ducting.
6. Design of burner, insulation, flue gas duct and reformer geometry. For details see [90].

Only a fraction of the heat supplied to the reformer furnace is used for reforming. A large amount of the heat in the flue gas is carried into the convection zone, where it is used to preheat the reformer feed, to produce and to superheat steam and, depending on circumstances at the site, maybe to preheat the combustion air.

The convection section can be installed as shown in Figure 21 (I – M). In most large hydrogen plants a flue gas fan must be installed, to induce the slight vacuum necessary for the draft burners and to compensate for the pressure drop over the heat exchanger coils in the convection section. For small plants, the convection section is sometimes installed on top of the reformer. This reduces the power requirements of the fan or allows design for natural draft.

The design of the convection section itself depends on the overall energy balance of the plant (see below) and the way the energy is to be utilized within the plant. This is influenced by the use of steam or electric drives or of gas turbines, etc. [91].

Energy Balance. The energy required for reforming in the furnace is (1) utilized as reforming energy and (2) in the convection section for preheating and steam production. In addition, energy losses such as insulation losses and the heat content of the flue gas lost through the stack must be considered. The efficiency factor for the steam reformer can be defined in several ways, for example:

Firebox Efficiency. The firebox efficiency is the ratio of energy necessary for reforming (Q_R) to the energy of fuel combustion (Q_{LHV}) (usually expressed in terms of the lower heating value of the fuel). If air or fuel are preheated it is necessary to consider the amount of energy brought in by preheated air Q_A, and/or preheated fuel Q_F to give:

$$\eta\,(\text{firebox}) = \frac{Q_R}{(Q_{LHV} + Q_A + Q_F)}$$

Firebox efficiencies lie in the range 0.45 – 0.55. This value only gives the relationship of the distribution of the energy between radiant and convection section, not, however, the degree of energy utilization.

Furnace Efficiency. The energy utilization in firebox and convection section is characterized by the overall furnace efficiency. This is the ratio of the sum of the utilized energy for reforming Q_R, for steam production Q_S and for any further energy utilization in the convection zone (e.g., feed preheating and superheating, export steam superheating, economizer Q_C) to the total energy supplied to the firebox

$Q_{LHV} + Q_A + Q_F$:

$$\eta(\text{furnace}) = \text{energy utilized}/\text{energy available}$$
$$= \frac{(Q_R + Q_S + Q_C)}{Q_{LHV} + Q_A + Q_F}$$
$$= (1 - \text{energy losses})/(\text{energy available})$$

The efficiency thus defined usually lies between 0.85 and 0.93 for hydrogen plants. The insulation losses are ca. 300 – 400 W/m^2 in the furnace section and ca. 600 – 700 W/m^2 in the convection zone which, depending on the size of the plant, amounts to ca. 1 – 5 % of the fired energy. The flue gas losses also vary with the size of the plant and the energy utilization and amount to 6 – 10 %.

Energy management plays a vital role in steam reformer design. The efficiency and the economy of the process are determined by the design variables, e.g., feedstock and fuel costs, bonus for export steam, use of electric or steam drives, S/C ratio, product gas pressure, etc. Suggestions for optimizing steam reformer plants can be found in the literature [92-94]. One typical example is discussed below.

4.1.3.3. *Steam Reforming Plant*

Figure 23 shows a simplified process flow diagram of a typical hydrogen plant. As in the majority of such plants, the feedstock is natural gas. Table 15 summarizes the process data. For the production of pure hydrogen, the following process stages are necessary:

Table 15. Mass balance of a typical steam reformer plant for the production of 5000 m^3 (STP)/h hydrogen. Feedstock: natural gas; byproduct: steam (3.0 MPa, 255 °C) 4700 kg/h (the numbers in Figure 23 denote the balance points)

	Feed, 1	Before desulfurization, 2	Reformer inlet, 3	Reformer outlet, 4	Pressure swing adsorption, 5	H_2 product, 6
H_2, vol %	0	4.8	1.1	51.9	74.6	99.99
N_2, vol %	1	1	0.3	0.2	0.25	0.01

Feed Preheating and Desulfurization. Usually, natural gas contains only small amounts of sulfur compounds, predominantly in the form of hydrogen sulfide. Because of the high sulfur sensitivity of the catalyst in the reformer (and in the LT shift reactor, if installed) hydrogen sulfide and other sulfur compounds must be removed on a zinc oxide bed (see Section Catalytic Gas Purification). If higher organic sulfur compounds (mercaptans, thiophene) or carbonyl sulfide in concentrations in the ppm-range are present, the zinc oxide bed alone is not sufficient and the sulfur compounds are converted to hydrogen sulfide in a hydrogenation stage. The hydrogen necessary is taken from the product stream and amounts to ca. 5 % for natural gas (whereas for naphtha and LPG 10 % and 25 % H_2, respectively, is used). Hydrogen recycle and hydrogenation also lowers the amount of olefins in the feed. The excess hydrogen in the feed helps to keep the reforming catalyst at the top of tube in a reduced state.

For hydrogenation and desulfurization the inlet gas is preheated to 350 – 400 °C. The gas leaves the purification section with a sulfur content of <1 ppm at essentially the same temperature.

Steam Addition, Reaction and Cooling. Steam is added to the inlet feed to give a ratio of 2.5 moles of steam per mole of carbon. This mixture can be further preheated in the convection section to 520 °C without cracking occurring. Reforming takes place in the reformer tube, the outlet temperature being 850 °C. After the reaction the gas is cooled quickly, thereby producing steam in the process gas boiler.

Water Gas Shift Reaction and Gas Purification.
High-Temperature Shift Conversion. The gas cooled down to 350 °C in the process gas boiler still contains a fair amount of carbon monoxide which can be converted into hydrogen by the water-gas shift reaction (Eq. 14, Table 14). An iron-oxide based catalyst is used for this. The shift reaction is usually carried out in a one-stage adiabatic reactor. Since the reaction is exothermic, the process gas temperature rises to 400 – 450 °C so the conversion is incomplete.

Pressure-Swing Adsorption (PSA). After high-temperature shift conversion, the gas is cooled down to ambient temperature. Water is condensed and removed before the gas is fed to at least three (but up to twelve) parallel adsorbers, which run in a predetermined cyclic operation. The various purge and decompression gases of the adsorbers are led into a large buffer vessel to compensate for variations in pressure and gas concentrations and are subsequently fired in the reformer along with a small amount of fuel gas for trimming purposes.

Classical Process. In an alternative route after the HT shift, the so-called classical process, the gas is cooled to ca. 220 °C and fed into a low-temperature shift reactor; followed by a carbon dioxide scrubber (monoethanolamine or hot potash, see Section Scrubbing Processes). The remaining impurities in the hydrogen, traces of carbon monoxide and carbon dioxide, are removed by a catalytic methanation step. Using this process, a hydrogen purity of 97 – 99 % can be attained (not taking the inert gases into account). Both process routes have been compared in the literature [92], [95], [96]. For pure hydrogen plants the PSA version has become standard. Plants are built according to the classical route only in special cases in which (1) the feedstock (natural gas, LPG, naphtha) is expensive, (2) a cheap fuel is available to fire the reformer, (3) carbon dioxide is a desired product, or (4) a hydrogen purity of <99.9 % can be tolerated. For the coproduction of carbon dioxide combinations of both processes have also been built.

Heating, Steam Production, Heat Management. In Figure 23 the fuel gas is essentially the purge gas of the PSA plant. In addition, small amounts of the feed gas are fired. The combustion air is preheated in the convection section up to 500 °C. The process gas boiler and the flue gas boiler produce the required process steam. Depending on the design conditions of the plant, export steam is available for other users. From the point of view of the heat balance, a hydrogen plant can be optimized to be self-supporting, for maximum production of export steam, for minimum hydrocarbon consumption, etc.

4.1.3.4. *Special Designs*

The general design of tubular steam reformers has changed little in the past 20 years. In particular new materials for reformer tubes, heat exchangers and insulation as well as better and fewer burners and a better heat management have led to a highly sophisticated type of plant with an excellent efficiency and reliability.

Nevertheless, many new designs have been developed although their economic importance is so far very limited. The main areas for improvement of the reformer are:

improvement of the heat transfer for the endothermic reaction,
reduction of the plant size,
reduction of the maximum temperature (at the burner and in the flue gas).

Pressurized Fireboxes. The pressure in the fireboxes of conventional tubular reformers is atmospheric or slightly below. The reasons for this are:

1. Simple construction and safe operation of the reformer furnace,
2. Simple sealing of large numbers of reformer tubes,
3. Purge gas (e.g., from the PSA) can be fired at the low pressure,
4. Induced draft burners or burners using combustion air at low pressures can be used.

The use of higher pressure in the firebox leads to higher heat transfer coefficients from the flue gas to the reformer tube by convection. Figure 24 shows the construction of such a reformer and a similar heat exchanger concept [97], [98].

Figure 24. Pressurized and heat exchange type reformers

A) KTI (Kinetics Technology International BV), United Technology Corp. version [99]; B) Haldor Topsøe AS, Denmark [97], [98]

a) Gas inlet; b) Reaction zone (circular zone[s]); c) Reformed gas outlet; d) Heating gas inlet; e) Combustion air; f) Burner; g) Radiant section; h) Section with forced convection; i) Flue gas outlet; j) Insulation

The catalyst is contained in the concentric space between the tubes so that the thermal expansion caused by start-up and shut-down of the reformer tube does not lead to sealing problems. Pressure on

the flue gas side is 300 – 500 kPa [99]. One disadvantage is that both fuel gas and combustion air must be compressed. Plants with a hydrogen capacity of 120 – 5000 m^3 (STP)/h (1.5 – 60 mol/s) have been built.

Helium-Heated Reformers. To utilize the heat of the high-temperature nuclear reactor for the production of hydrogen from methane, a reformer with helium heating has been suggested. Since the helium temperature at the present stage of development is 900 °C, only a small temperature difference is available for the heat transfer. The reformer is similar to a conventional tube bundle reactor [100], however, the construction is very complex for safety and other considerations. Principally speaking, the reactor and heat exchanger could be used for other endothermic reactions. Up to now, only two prototypes with a capacity of 0.8 and 10 MW have been in operation. The helium is heated electrically in these plants.

Electrically Heated Reformers. For the production of small quantities of hydrogen electrically heated reformers have been suggested [101]. The hot product gas is used to heat the feed gas and produce part of the steam required. The energy requirement of ca. 300 kJ per mole of hydrogen is less than for a conventional steam reformer or for the electrolysis, whereby 80 kJ are brought in electrically and 220 kJ correspond to the lower heating value of the hydrocarbon used. However, it should be pointed out, that fossil and electrical energy can be compared on an equivalent basis only under special conditions.

Steam Reforming with Integrated Hydrogen Separation. High-temperature-resistant membranes have been integrated in a tubular reformer. Thus, hydrogen is withdrawn from the reaction mixture as it is formed. The chemical equilibrium is permanently shifted towards a higher feedstock conversion. For this reason either lower temperatures can be used or higher yields can be obtained. Palladium foil (100 µm) on a porous cylinder inserted into the reformer tube has been suggested as a suitable membrane. A small laboratory-scale plant has been built and successfully tested [102].

4.1.3.5. *Autothermal Reactors*

In autothermal reactors (secondary reformers) the energy for the production of carbon monoxide and hydrogen is produced by catalytic partial oxidation of part of the feedstock.

This type of reactor is employed:

1. to achieve high equilibrium temperatures (up to 1000 °C) thus minimizing methane concentration,
2. to enable use of elevated pressures (up to 5 MPa) together with high equilibrium temperatures (900 – 1000 °C) not feasible in fired steam reformer tubes,
3. to introduce nitrogen for the production of a stoichiometric syngas mixture for the ammonia synthesis.

In the first two cases the reactor is operated with pure oxygen (and steam). In the third case air or turbine off-gases are used. Figure 25 depicts three different types of autothermal reactor.

Figure 25. Designs of secondary (autothermal) reformers

A) Water-cooled jacket reactor with burner for methane-rich gases; B) Secondary reformer with toric oxygen or air supply device [90]; C) Secondary reformer with water-cooled tip without water jacket [103]

a) Raw gas inlet; b) Reformed gas outlet; c) Air, oxygen, and steam inlet; d) Catalyst; e) High-temperature catalyst; f) Inert material; g) Internal insulation; h) Multiple layers insulation; i) Burner; j) Water jacket

With the reactors shown in Figure 25 A and B no reaction occurs before the gas enters the catalyst bed. Reactor C features a burner, thus thermal oxidation takes place in the empty space above the catalyst bed. In all cases the highest temperatures occur at the top of the reactor because of the catalytic (A, B) or thermal oxidation (C) of hydrogen and carbon monoxide. The endothermic reforming of methane and other hydrocarbons according to the steam – methane equilibrium (Eq. 7 Table 14) is carried out in the lower part of the reactors. Nickel catalysts are used, often in the form of impregnated alumina lumps, which have a high resistance to fusion and thermal shock.

The waste-heat boiler is mounted immediately after the reactor, usually without a transfer line. Synthesis gas cools down rapidly in the boiler, thus avoiding recombination of carbon monoxide and hydrogen.

The direct application of the catalytic autothermal reactor without preceding decomposition of at least part of the hydrocarbons in a primary reformer has been studied in experimental plants [104]. Several layers of catalyst with increasing activities are used. Soot formation and high-peak temperatures are avoided by using a suitable catalyst at high space velocities, even though benzene feedstock, which is particularly liable to soot formation at a low S/C ratio is used. The experimental results are depicted in Figure 26. Because of the high reaction temperature the secondary reformers can stand a higher sulfur concentration in the feedstock. This fact has led to several tests with high-sulfur feedstock. However, commercial application has not yet been realized [76], [77].

Figure 26. Autothermal reforming of benzene on Ni-catalysts of increasing activity [104]

4.1.4. *Refinery Processes*

In refineries some processes require hydrogen, while others are a potential source of hydrogen. With the increasing quality demands for refinery products and with the increasing use of bottom-of-the-barrel products, the transfer of hydrogen within the refinery is increasing. Hydrogen is produced by steam reforming of hydrocarbons and by recovery from hydrogen-rich gases and refinery offgases, formerly used as heating gases, (Chap. Purification of Hydrogen).

Production and recovery of hydrogen from the byproducts of the following types of refinery processes are possible:

cokers and visbreakers
(thermal cracking processes)
catalytic crackers
catalytic reformers

For a detailed description of the processes see ⟶ Oil Refining. Here only facts relating to the hydrogen production are discussed.

Cokers and Visbreakers. In cokers and visbreakers heavy crude and residues are converted to petroleum coke, oil, light hydrocarbons (benzene, naphtha, LPG) and gas. Depending on the process, hydrogen is present in a wide range of concentrations. Since (like the coal coking process) petroleum coking processes need gas for heating purposes, adsorption processes (PSA) are best suited to recover the hydrogen because they feature a very clean hydrogen product and an off-gas suitable as fuel (see Section Coke Oven Gas).

If more hydrogen is required in the refinery, it can be derived from the fuel gas and from the LPG fraction by steam reforming. In times of oil shortage processes have been suggested to convert the excess coke into synthesis gas and hydrogen by coke gasification [105], [106].

Catalytic Crackers. Catalytic cracking is the most important process step for the production of light products from gas oil and increasingly from vacuum gas oil and residues.

In catalytic cracking the molecular mass of the main fraction of the feed is lowered, while another part is converted to coke. The coke is deposited on the hot catalyst. The catalyst is regenerated in one or two stages by burning the coke off with air, which also provides the energy for the endothermic cracking process. The cracking processes occurring can be categorized as follows [107]:

paraffins and naphthenes are cracked to olefins and to alkanes with shorter chain length,
monoaromatic compounds are dealkylated without ring cleavage,
diaromatics and polyaromatics are dealkylated and converted to coke.

Hydrogen is *formed* only in the last type of reaction, whereas the first two reactions produce light hydrocarbons and therefore *need* a certain amount of hydrogen. Figure 27 shows for various feedstocks, that an increase in coke production goes hand in hand with an increase in hydrogen production. Thus, a catalytic cracker can be operated in such a manner that enough hydrogen for subsequent processes is formed.

Figure 27. Hydrogen production vs. catalytic coke yield using amorphous catalyst for different feedstocks [108]; ○ West Texas Permian; △ Light Iranian; ▪ Kuwait; ● Residuum

Figure 28 shows how the hydrogen production from catalytic cracking can be linked to other hydrogen consuming processes. After desulfurization by absorption processes (see Section Scrubbing Processes) the off gas is usually purified and fractionated in a cryogenic unit (see Section Low-Temperature Processes).

Figure 28. Hydrogen production by catalytic cracking with subsequent use in hydro-desulfurization processes

——H_2-rich gases; —— H_2 purified

Catalytic Reformers. Naphtha fractions are reformed to improve the quality of gasoline. The most important reactions occurring during this process are the dehydrogenation of naphthenes to aromatics. For the dehydrogenation of cyclohexane, e.g., the hydrogen formation is as follows:

$$C_6H_{12} \rightarrow C_6H_6 + 3\,H_2 \quad \Delta H = +206.20\,\mathrm{kJ/mol}$$

This reaction is endothermic and is favored by low pressures. However, because hydrocracking occurs as a concurrent reaction the pressures are chosen between 1 and 3 MPa and the reaction temperature lies in the range of 300 – 450 °C. The reaction is performed on platinum catalysts, with other metals, e.g., rhenium, as promoters. The feedstock for the reforming process must be carefully purified from sulfur and nitrogen compounds (both <1 ppm). This uses up a great deal of the hydrogen produced. Table 16 summarizes the results of some reforming processes. The aromatic content of the feedstock is substantially increased and the hydrogen set free raises the content in the off-gas to 85 %.

Table 16. Hydrogen as a byproduct of catalytic reforming processes. Range of production and composition of the H_2-rich gas fraction

	Range	
Feedstock: naphtha		
Boiling range, °C	80 – 200

CH_4, vol %	5 – 9	7
C_2, vol %	4 – 7	5
C_3, vol %	2.5 – 5.5	4
C_4, vol %	0.5 – 2.5	2

4.1.5. *Petrochemical Processes*

Steam Cracking for Olefin Production. During the production of ethylene (⟶ Ethylene) and propene (⟶ Propene) large amounts of hydrogen are formed as byproduct. The composition of some crude gases from steam cracking of ethane, naphtha and hydrogenated vacuum gas oil is given in Table 17.

Table 17. Hydrogen as a byproduct in the production of ethylene in modern short residence time cracking furnaces. Cracking conditions standardized to an ethylene yield of 32 %

Raw gas	Ethane	Naphtha	Gas oil
After cracker and dryer			
H_2, mol %	33	16	10
CH_4, mol %	5	32	30
C_2H_4, mol %	32	32	32
C_2H_6, mol %	28	5	6
C_3H_6, mol %	1	11	16
C_3H_8, mol %		1	1
Other: C_{4+}, CO, H_2S, mol %	1	3	5
H_2-fraction of demethanizer			
H_2, mol %		80 – 95	
CO, mol %		1 – 0.5	
CH_4, mol %		19 – 4.5	
C_2, mol %		0.1	

Since propane, propene, ethane, and ethylene are fractionated at low temperature, hydrogen is usually separated from methane by condensation of the latter (see Section Low-Temperature Processes). The hydrogen recovered has a purity of 90 – 96 %.

Acetylene Production. Hydrogen is also produced as byproduct in the production of acetylene by thermal cracking (⟶ Acetylene, ⟶ Acetylene – Production from Liquid Hydrocarbons (Plasma Arc Process)). Because of the extreme cracking conditions the hydrogen content in the crack gas is particularly high. The production of 120 000 t/a acetylene and 50 000 t/a ethylene using the Hüls electric arc process yields 360×10^6 m^3 (STP)/a hydrogen as byproduct. In Table 18 the crude gases of several processes are compared. The acetylenes are recovered from the raw gas by absorption. Pure hydrogen is recovered from the remaining gas by cryogenic processes, sometimes in combination with adsorption processes.

Table 18. Hydrogen as a byproduct in acetylene production (raw gas after quench and condensation, dry basis)

[a] 1460 m^3 (STP) H_2 per tonne of feed.

[b] 3300 m^3 (STP) H_2 per ton of C_2H_2, 1830 m^3 (STP) H_2 per tonne of feed

In a further development of the electric arc process for the production of hydrogen, reduction gas, acetylene and ethylene, a plasma process has been suggested. A great number of feedstocks can be used ranging from natural gas to coal [109], [110]. The hydrocarbons are not cracked directly in the arc but a hydrogen plasma is used as energy carrier. In this way the acetylene yield can be increased while the hydrogen yield (and the amount of carbon deposits) decrease.

4.2. Electrolysis

Electrolysis has been used for approximately 100 years for hydrogen production. The first large installation was by Norsk Hydro in 1927 in Norway. Further plants were erected by Cominco in Trail, British Columbia, Canada in 1940 and, from 1945 onwards, some other plants with capacities up to 33 000 m^3 (STP)/h of hydrogen. As explained in Section Economic Aspects, the erection of large electrolysis plants depends on the availability of cheap electricity from hydropower stations. Plants for smaller amounts of hydrogen (50 – 500 m^3 (STP)/h) are often used by the industry because they are simple to operate. Moderate power costs are an additional incentive. A total of ca. 5 % of the world hydrogen production is by means of electrolysis.

4.2.1. *Principles*

For general principles see ⟶ Electrochemistry.

If a potential is applied to the electrodes of an electrolysis cell filled with a suitable electrolyte, the following reaction occurs at the electrodes:

1. Cathode

$$2\,H_2O(l) + 2\,e^- \rightarrow H_2(g) + 2\,OH^-(aq) \tag{26}$$

2. Anode

$$2\,OH^-(aq) \rightarrow 1/2\,O_2(g) + H_2O(l) + 2\,e^- \tag{27}$$

3. Cell Reaction

$$H_2O(l) \rightarrow H_2(g) + 1/2\,O_2(g) \tag{28}$$

where l is liquid, g is gaseous, and aq is dissolved in water.

Pure water is not suitable as an electrolyte because of its very low conductivity. Therefore, aqueous solutions of potassium or sodium hydroxide, sodium chloride, hydrochloric acid, etc. are used. Depending on the electrolyte and the material of the electrodes the reaction at the anode may lead to other products, in particular to sodium hydroxide and chlorine (see Section Hydrogen as Byproduct from other Electrochemical Processes).

The change in enthalpy for the electrochemical decomposition of water is

$$\Delta H = \Delta G + T\Delta S = -nFE + nFT\cdot\left(\frac{\partial E}{\partial T}\right)_{\mathrm{p}} \tag{29}$$

where *H* is the enthalpy, *G* is Gibbs free energy, *S* entropy, *T* temperature, *n* number of electrons transferred per formula conversion, *F* the Faraday constant, and *E* the electrochemical potential.

The thermodynamic standard data at *p* = 101.3 kPa and *T* = 298.15 K are:

Reaction enthalpy = $\Delta H^0_{298\,\mathrm{K}} = 286\,\mathrm{kJ/mol}$

Reaction entropy = $\Delta S^0_{298\,\mathrm{K}} = 163\,\mathrm{Jmol^{-1}K^{-1}}$

Gibbs free energy of reaction = $\Delta G^0_{298\,\mathrm{K}} = 237\,\mathrm{kJ/mol}$

The value of the Faraday constant is

$$F = 96495\,\mathrm{As/mol}$$

Using these data the required electrical energy becomes:

$$W = \Delta G = F \times n \times E_{\mathrm{rev}} \tag{30}$$

where E_{rev} is the ideal (reversible) decomposition potential. Under standard conditions it amounts to:

$$E_{\mathrm{rev}} = \frac{\Delta G}{n\cdot F} = 1.228\,\mathrm{V} \tag{31}$$

Because of irreversible processes on the electrodes and because of the resistance of the electrolyte the actual decomposition potential is always higher than the ideal value.

According to Equation (29) the free energy, ΔG, is smaller than the reaction enthalpy, ΔH, by the amount $T\,\Delta S$. In the ideal case operation of the cell requires an amount of electrical energy, $W = \Delta G$, and the addition of heat, $Q = T\,\Delta S$.

If both amounts of energy are to be supplied in the electrical form, the potential under standard conditions is increased by the thermal potential ΔE_Q.

$$\Delta E_{\mathrm{Q}} = \frac{T\Delta S}{n\cdot F} = 0.252\,\mathrm{V} \tag{31a}$$

Thus, the theoretical minimum decomposition potential at standard conditions is:

$$E_{\mathrm{th}} = 1.480\,\mathrm{V}$$

Figure 29 shows the temperature dependence of the energy or the decomposition potential, respectively at a constant pressure of 100 kPa. An increase in temperature lowers the reversible decomposition potential, while at the same time the thermal fraction of the total energy required increases. This means, that at higher temperatures heat energy instead of electrical energy can be partially used. Technical aspects of this behavior in regions above the boiling point of water (373 K) will also be considered in more detail in Section New Developments in Electrolytic Processes .

Figure 29. Temperature dependence of hydrogen formation by electrolysis at 101.3 kPa. The energy scale (kJ/mol) shows the standard free energy ΔG^0 and the enthalpy ΔH^0 of water cleavage. The voltage scale (V) allows determination of the corresponding theoretical cell voltage

a) Formation with H_2 heat output; b) H_2 formation with heat input necessary; c) No H_2 formation by electrolysis possible

The decomposition potential also depends on pressure. From the pressure dependence of the free energy

$$\left(\frac{\partial \Delta G}{\partial p}\right)_T = \Delta \mathrm{v}$$

the following expression can be derived for the pressure dependence of the decomposition potential of an ideal gas, i.e., neglecting the activity coefficients:

$$\Delta E_p = \Delta E^0 + \frac{RT}{2F} \ln \left\{ \frac{p_{(H_2)}}{p^0} \cdot \left[\frac{p_{(O_2)}}{p^0} \right]^{1/2} \right\}$$

For water at 298 K, taking the activity coefficients into account this equation becomes

$$\Delta E_p = \Delta E_{(p=p^0)} + 0.0189 \ \ln \frac{p}{p^0}$$

so that, on increasing the pressure from 100 to 1000 kPa, an increase of 0.0435 (= 0.0189 · ln 10) V would be expected. However, the fact that the gas produced at the electrodes has a smaller effective volume leads to a reduced overpotential at the electrodes, so that for electrolysis under increased pressure no increase in the total potential is in fact found.

The potential actually required is the sum of the following contributions:

$$U = E_1 + E_2 + E_3 + E_4$$

where U is the cell voltage (V), E_1 the theoretical cell voltage (E_{rev}) (V), E_2, E_3 the anodic and cathodic overvoltage (V) at the phase boundary electrolyte-electrode, and E_4 is the voltage drop (V), due to electrical resistance of the electrolyte system.

The overvoltages E_2 and E_3 can be influenced by suitable choice of the electrode materials and their surface conditions. The voltage drop in the electrolyte, E_4, depends (1) on the conductivity of the electrolyte, (2) on the permeability of cell diaphragms, (3) on the distance of the electrodes from one another, and (4) on the current density. Figure 30 shows the influence of the current density on the cell voltage during water electrolysis using potassium hydroxide electrolyte.

Figure 30. Relationships between current density and cell voltage for alkaline water electrolysis

—— conventional electrolysis, 30 wt % KOH, 90 °C; – – – prognosis for advanced conventional electrolysis according to [111], [112]

E_1 theoretical reversible cell voltage; E_2 anodic overvoltage, difficult to minimize; E_3 cathodic overvoltage, can be reduced by suitable catalysts; E_4 resistance of the electrolysis system, can be reduced by the use of thin-walled diaphragms and zero-gap constructions

The efficiency of the electrolysis is related to the minimum voltage according to Equation (29):

$$\eta = \frac{E + \frac{T \Delta S}{n F}}{U}$$

Under standard conditions:

$$\eta = \frac{1.48}{U} \frac{\mathrm{V}}{\mathrm{V}}$$

Principle Construction of a Water-Electrolysis Cell. Figure 31 shows the principal construction of a cell. Anode and cathode regions are separated by a diaphragm which allows the current to flow, but is otherwise gas-tight. The cell is filled with electrolyte. Oxygen is formed during the electrolysis at the anode, hydrogen at the cathode. Depending on the arrangement of the electrodes and the diaphragm, the cells may be designated as unipolar or bipolar cells (see Fig. 32).

Figure 31. Schematic of a water electrolysis cell

a) Cell walls; b) Electrolyte; c) Cathode; d) Anode; e) Hydrogen outlet; f) Oxygen outlet; g) Gas collector; h) Diaphragm; i) Outer cathode; j) Outer anode; k) Bipolar electrode; l) Insulation

The *unipolar cells* are further differentiated in bell-type (without diaphragms), the usual diaphragm cells, and a bell-diaphragm type. A characteristic of the unipolar cell is that cathode and anode each have their own separate cell region.

Bipolar cells are characterized by the fact that the metallic separator between two cells connected in series serves as cathode in one of the cells and as anode in the next cell. The arrangement of the bipolar electrodes is similar to the construction of a filter press, so that they are often named accordingly.

Electrolyte. To minimize the resistance losses of the electrolytes usually 25 – 36 wt % potassium hydroxide solution is used. Other electrolytes are aqueous sodium hydroxide or, for the chlor-alkali electrolysis, solutions of hydrochloric acid, sodium chloride, etc. Electrolytes which are immobilized in polymers can also be used.

Since the conductivity of conventional electrolytes increases with temperature, electrolysis units usually operate at 70 – 90 °C, just below the boiling point of the aqueous solution. The conductivity of sodium hydroxide and potassium hydroxide as a function of temperature and electrolyte concentration is shown in Figure 33.

Figure 33. Conductivity of electrolytes used in conventional water electrolysis

a) NaOH, 40 °C; b) NaOH, 60 °C; c) NaOH, 80 °C; d) KOH, 60 °C; e) KOH, 80 °C

Materials. Electrochemical processes place particularly high requirements on corrosion protection. The conventional water electrolysis with potassium hydroxide as electrolyte can be carried out using carbon steel as a material of construction. Areas particularly subject to attack are coated with plastics or ceramics or are nickel-plated.

The cathode is usually made of steel. To reduce the hydrogen overvoltage E_3 the surface texture may be activated and coated with various catalysts. The anode and the electrodes of bipolar cells are usually made of nickel or nickel-coated steel. Next to platinum, which cannot be used for economic reasons, this material has the lowest overvoltage.

The diaphragm in the classical electrolysis units was initially made of asbestos. The asbestos mats, which separate the electrodes from one another, were reinforced with nickel nets. Because of the health hazards involved in the use of asbestos, substitute materials are being looked for. Ceramics and hydrophiliated polymers may be the solution to this problem.

4.2.2. *Conventional Water Electrolysis*

A conventional electrolysis system uses an alkali solution, usually potassium hydroxide, as electrolyte. The electrodes are in unipolar or bipolar arrangements. Hydrogen production takes place either at ambient or at increased pressure (Commercial plants up to 3 MPa).

Normal-Pressure Electrolysis Units. The advantages of a process at almost ambient pressure are:

1. Low mechanical strains on piping fittings, seals, and instruments,
2. Simple operation, because feed water is not required under pressure, quick start-up, simple maintenance,
3. Safer operation because of avoidance of high-pressure hydrogen, small pressure differences between the evolved gases, and simple blanketing of the electrolysis units and the piping network with nitrogen under low pressure

Unipolar Stuart cells are offered by a single producer (Electrolyser Inc., Toronto). The particular advantage of this type of cell is its robust nature. Since the cells are arranged in parallel they can be easily maintained or renewed, if necessary, without interruption of the process.

All other producers use *bipolar cells* which are mounted in series (filter press). This allows the use of higher voltages (up to 600 V) per unit. A schematic of bipolar electrolysis is shown in Figure 34. Pre-electrodes, which are placed close to the diaphragm to give the smallest possible resistance between the electrodes, can be clearly seen. The electrodes themselves are perforated or made from nets, so

that the gas bubbles evolve behind the electrodes and do not increase the resistance between the electrodes.

Figure 34. Cross section of a bipolar, atmospheric pressure electrolysis unit with alkaline electrolyte (Brown Boveri)

a) First anode with pre-electrode; b) Diaphragm; c) Pre-electrode of the cathode; d) Cathode for the first cell compartment and anode for the second cell compartment-bipolar middle electrode; e) Cell frame with insulation for the middle electrode; f) Distribution pipe for electrolyte; g) Inlet pipe for electrolyte; h) Take-off system for electrolyte and dissolved gases; i) Overflow pipe and collecting vessel for electrolyte and H_2 (an analogous system is used for O_2); j) Electrolyte filter; k) Circulation pump; l) End plate

The operating conditions for electrolysis units of various producers are given in Table 19 (see also ⟶ Electrochemistry). Typical operating conditions are electrolyte temperatures of 70 – 90 °C, a cell voltage of 1.85 – 2.05 V and a current density of 2 – 3 kA/m^2. The specific power consumption is between 4 and 5 kWh/m^3 (STP).

[a] Much larger plants have been built by combining the appropriate number of units.
[b] No up-to-date information available.
[c] Higher value: standard electrode; lower value: activated.

It must be taken into account whether the energy consumption is only for the electrolysis itself, or whether further installed units, such as electrolyte pumps, water treatment plant, gas purification, are included.

The gas purity after compression and water removal is in general > 99.8 % for hydrogen and > 99.6 % for oxygen. Higher purities are possible by means of catalytic conversion and/or adsorptive drying

units.

Pressure Electrolysis. Pressure electrolysis units in the range of 0.6 – 20 MPa are available. Since hydrogen is usually required at high pressure, and because the power consumption for the pressure electrolysis does not increase significantly, these units save both equipment and energy for hydrogen compression. The construction and the sealing of the electrolysis cells, however, is complicated (see Fig. 35). The operating data reported by producers of pressure electrolysis are given in Tables 19 and 20. To compare the data with those of low pressure electrolysis the energy consumption for hydrogen compression to the end pressure has to be considered.

Advanced Conventional Electrolysis. The conventional potassium hydroxide electrolysis according to [113], [114], can be improved considerably. Some of the suggestions made have been incorporated in single commercial electrolysis units. Other components necessary are still in the development stage. Areas of development are:

Zero-Gap Cell Geometry. By placing the electrodes directly on the surface of the diaphragm the space between the electrodes can be reduced and the voltage drop in the electrolyte, and thus the heat loss caused by the current, can be minimized. Figure 36 shows perforated foil electrodes in a zero-gap construction.

Figure 36. Zero gap cell geometry. Perforated cathodes and anodes, similar to the nets in Figure 35, in direct contact with the diaphragm and the membrane, respectively. The conical apertures with different diameters for O_2 and H_2, respectively, facilitate the detatchment of the developing gas bubbles [113]

In particular the construction with pre-electrodes has already been used in commercial plants. The disadvantage of this type is that in these electrolysis units, with high current density and high operating temperatures, the corrosion tendency is greatly increased. Products of corrosion, which may be formed at the anode, can grow through the diaphragm and lead to dangerous short-circuits.

New Materials for Diaphragms. A replacement for asbestos diaphragms are polysulfones, with hydrophobic character decreased by means of additives (e.g., polyantimonic acid) [115].

Another line of development is the use of oxide-ceramic diaphragms based on barium or calcium titanate or nickel oxide [116]. On a metallic net a hydrophilic gas-tight oxide layer is deposited. The thickness of the layer is <500 µm, which leads to a low resistance of ca. $2\times10^{-5}\ \Omega/m^2$. The stability against electrolytes at high temperatures is also favorable.

Electro-Catalysts. The kinetic inhibition of the electrode processes can be reduced by use of catalysts. This is already partly done in conventional plants. To assist the oxygen formation at the anode, lanthanum-containing perowskites, nickel-cobalt oxides and Raney nickel has been suggested.

The overvoltage at the cathode during the evolution of hydrogen can be reduced by the use of noble metals (platinum black). Commercial catalysts are, however, free of noble metals. Sintered, foamed, and alkali-leached nickel compounds, which are stabilized by the addition of TiO_2, ZrO_2 and MoO_3, are used. The long-term stability and the corrosion resistance against hot alkali solutions expecially in the depolarized state are the main problems encountered in the use of electro catalysts.

The increase in capacity of the new types of electrolysis cells makes further improvements necessary. The increased corrosion caused by the higher operating temperatures and greater current densities requires special materials of construction. In large-capacity plants nickel-plated steel, in low-capacity plants (≤ 20 m^3 [STP]) polysulfone, is employed. In particular, the gas collection system for the fine hydrogen bubbles necessitates additional equipment.

If all the theoretical possibilities to improve the electrolysis were employed, the water electrolysis could be greatly improved. Region b in Figure 37 shows the boundaries of the improvement possible in alkaline water electrolysis [113], [114].

Figure 37. Illustration of the cell voltage and current density of commercially available or projected electrolysis units

Electrolysis Plants (see Fig. 38). Apart from the electrolysis unit an electrolysis plant consists of a number of different installations, such as electricity supply, water treatment, electrolyte circulation, the knock-out system (phase separator) to separate electrolyte from the product gases, gas purification, and the instrument and control system.

Figure 38. Process diagram of an electrolysis unit with the most important components

a) Rectifier unit; b) Process water demineralizer ion exchange unit; c) Electrolytic cell's water electrolyzer; d) Gas separator and cooler; e) Gas scrubber; f) Electrolyte tank and transfer pump; g) Gas holder; h) Filter; i) Compressor; j) Gas purifier; k) Drying; l) High-pressure storage tank and cylinder filling station

The water consumed during electrolysis has to be continuously replaced; the consumption is 0.805 L per cubic meter of hydrogen plus evaporation losses. The water make-up must meet stringent purity

requirements to avoid a build-up of substances in the electrolyte solution which poison the electrodes or promote corrosion. The required water purity (conductivity 1 µS/cm) is obtained with the aid of ion exchangers.

The power, which in large plants is supplied in the form of three-phase current at a high voltage, must be transformed and rectified down to the necessary d.c. voltage. In addition, power for the various auxiliary equipment, such as the electrolyte circulation pump and the instrument and control system is necessary. Considerable amounts of potassium hydroxide are only necessary for the first filling. Since the energy losses in the electrolyte are converted to heat, a large amount of cooling water is necessary to operate the plant. This is also true for the gas purification unit.

The *gas purification* depends on the purity requirements placed on the gas and may be a simple condensation to remove moisture present. For higher purity requirements the catalytic conversion of the oxygen present in the hydrogen (see Section Removal of Oxygen) and, after that, an adsorptive drying stage (Section Thermally Regenerated Adsorbers) is used.

4.2.3. *New Developments in Electrolytic Processes [117], [118]*

Electrolysis with Proton-Conducting Ion-Exchange Membranes. In this type of electrolysis, better known as solid polymer electrolysis (SPE, General Electric), the diaphragm is replaced by a proton-conducting ion-exchange membrane (⟶ Electrochemistry, ⟶ Fuel Cells – Proton Exchange Membrane Fuel Cells (PEMFC)). The water to be electrolyzed is introduced only to the anode side, and no additives to alter the conductivity are necessary.

The solid electrolyte consists of a Nafion membrane with the approximate structure:

A cell consists of a ca. 0.25 mm thick film of this polymer. The following substances have been reported as electrode and catalyst material: platinum metal (cathode), and ruthenium oxide hydrate (anode).

The electrode layers have a high specific surface. The membrane becomes saturated with the water added at the anode side, which is electrolyzed and serves as a cooling medium at the same time. The electrical charge is transported by means of the hydrated H^+ ions of the sulfonic acid groups. Current densities of up to 20 000 A/m^2 can be reached. The principal construction of the electrolysis cell is shown in Figure 39 using the Membrel electrolysis (Asea Brown Boveri) as an example [119].

Figure 39. Principles and construction of an SPE electrolysis unit, Type: Membrel, Asea Brown Boveri [119].

At too high voltages ozone is produced at the anode

a) Porous cathodic current collector; b) Membrane, solid state electrolyte; c) Porous anodic current collector; d) Catalyst

The electrodes are in contact over the whole surface with a porous conductor; this is graphite on the cathode side and sintered nickel or titanium on the anodic side. The electrodes are in a bipolar arrangement.

Electrolysis units with proton-conducting membranes are offered in a capacity up to about 5 m^3/h of hydrogen from various producers. The characteristic operating data of such a module and of a conventional electrolysis unit are compared in Table 21. The advantages of these SPE units are not so much in the savings in power, but especially in the reduced volume of the unit, due to the much higher current density and the size reduction attainable because of the absence of the potassium hydroxide electrolyte system.

Table 21. Comparison of conventional potassium hydroxide electrolysis with electrolysis using polysulphone electrolyte and membranes

	BBC KOH electrolysis	ABB Membrel electrolysis	Hydrogen appliances SPE electrolysis
Electrolyte	25 wt % KOH	polysulfone Nafion	polysulfone Nafion
Temperature, °C	80	80	50
System pressure, MPa	0.1	≤2.0	2.5
Current density, A/m^2	2000	10 000	

Cell voltage, V	2.05	1.74	
Efficiency (η = 1.48/*U*), %	72	85	
Energy consumption (3.54/ η), kWh/m^3 (STP)	4.9	4.2	4.2 (at 20 % efficiency) 5 kWh/m^3 (STP) (at 100 % efficiency)
Block volume	30		

Further developments are proceeding in this direction. For example, in test plant modules used in the Japanese Sunshine Project [120], membranes and catalysts have been operated at current densities up to 20 000 A/m^2 and temperatures up to 150 °C.

Solid polymer electrolytic cells can also be used advantageously, for the coproduction of ozone (O_3) if the appropriate overvoltage is applied (see also Fig. 39).

Water Vapor Electrolysis. According to Equation (29) the total energy requirement for electrolysis is only slightly temperature-dependent. However, the reversible part of the energy i.e., ΔG, which must be supplied in the form of electrical energy, decreases with increasing temperature (see. Eq. 31 a and Fig. 29). This means that an increasing amount of the total energy can be supplied by thermal energy. Overvoltages, which result from kinetic inhibition, also decrease with increasing temperature.

In the conventional alkali electrolysis the reaction temperature is limited because of the vapor pressure of the electrolyte and corrosion problems. Thus, for the asbestos-diaphragm cell the upper temperature limit of operation is 120 °C. For the polysulfone membrane the upper temperature limit is ca. 150 °C.

In high-temperature electrolysis doped zirconium dioxide and some other rare earth oxides are used as electrolyte. At temperatures >800 °C ZrO_2 and some other rare earth oxides are oxygen ion conductors (lattice defect conductors). In Figure 40 the specific resistance of some mixed oxides is given. These mixed oxides are sintered into ring-shaped membranes, which are kept as thin as possible (0.5 mm, goal is 20 – 30 µm [121]) to reduce the electrical resistance of the cell. The rings are built up into tubes and the tubes to bundles of cells (Fig. 41).

Figure 40. Specific resistance *r* (Ω cm) of various solid state electrolytes with oxygen-ion conductivity as a function of temperature [122]

a) $(ThO_2)_{0.93}(Y_2O_3)_{0.07}$; b) $(ZrO_2)_{0.88}(CaO)_{0.12}$; c) $(ZrO_2)_{0.90}(Y_2O_3)_{0.10}$; d) $(ZrO_2)_{0.92}(Yb_2O_3)_{0.08}$

Figure 41. Principles and construction of a bipolar high-temperature electrolysis cell with an oxygen-ion conductive ZrO_2 electrolyte

a) Anode; b) Electrolyte (ZrO_2); c) Cathode; d) Insulation; e) Conductive cell sections; f) O_2 space; g) H_2, H_2O duct

Porous electrodes are positioned on the surface of the solid electrolyte. Mixed oxides with perovskite structure are used ($LaNiO_3$, $LaMnO_3$) for the anode. The cathode is a ZrO_2/Ni cermet, which prevents the active nickel metal of the cathode from agglomerating [123]. Water vapor is led to the *cathode*, whereby the cathode reaction for hydrogen formation takes place:

$$H_2O + 2e^- \rightarrow O^{2-} + H_2$$

The oxygen ion is oxidized at the anode:

$$O^{2-} \rightarrow 2e^- + 1/2\,O_2$$

Typical operating conditions are:

Potential	1.3 V
Current density	0.4 A/cm^2
Operating temperature	900 °C
Electrical energy consumption	ca. 3 kWh per cubic meter (STP) H_2

The performance characteristics of the high-temperature electrolysis is also given in Figure 37.

The process has been tested on a laboratory scale [124-126]. A pilot plant for the production of 1 m^3 (STP) hydrogen per hour is under construction. A 3.5 MW pilot plant is planned [127] but a number of material problems must be solved before realization.

The reversal of this process is expected to have a potential in fuel cell applications. This applies to the aforementioned solid polymer electrolysis as well (⟶ Fuel Cells – Proton Exchange Membrane Fuel Cells (PEMFC)). The direct production of electric power from hydrogen, carbon monoxide or hydrocarbons with air or pure oxygen in fuel cells of this type is still in the first stages of development.

4.2.4. *Hydrogen as Byproduct from other Electrochemical Processes*

See also ⟶ Electrochemistry; ⟶ Chlorine.

Electrochemical processes for the production of sodium hydroxide, chlorine and chlorine compounds yield hydrogen as a byproduct. About 3 % of the world hydrogen production, but a higher percentage of the merchant hydrogen, is produced in this way. The economically most important electrolysis is the chlor – alkali process. At present there are three different commercially important technologies to produce sodium hydroxide and chlorine.

In the *mercury process*, hydrogen is generated by decomposition of sodium or potassium amalgam, which is itself formed in a concurrent reaction to the kinetically strongly inhibited direct hydrogen evolution (32) on the mercury cathode (33).

$$2\,H^+ + 2\,e^- \rightarrow 2\,H \rightarrow H_2 \tag{32}$$

$$Hg_x + Na^+ + e^- \rightarrow NaHg_x \tag{33}$$

$$2\,NaHg_x + 2\,H_2O \rightarrow 2\,NaOH + H_2 + 2\,Hg_x \tag{34}$$

The decomposition reaction (34) is carried out in either horizontal or vertical decomposers. Because of the hydrogen overvoltage, a catalytically active decomposition material (technically graphite) is used and high temperatures are necessary. Hydrogen from the amalgam decomposers must be freed from mercury [to <0.002 mg Hg/m^3 (STP)] by cooling, scrubbing with brine and use of iodine-activated charcoal or a catalytic process.

In the *diaphragm process*, in which the overall reaction (35) occurs, hydrogen is formed on a hollow cathode made of iron, which is separated from the anode region by a diaphragm.

$$NaCl + H_2O \rightarrow 1/2\,H_2 + 1/2\,Cl_2 + NaOH \tag{35}$$

Both processes are, at this time, being replaced by the membrane process because of environmental and economic reasons.

The *membrane process* accounted for 10 % of the world capacity in 1987. New plants projected are based almost exclusively on the membrane process. Figure 42 shows the principal reactions and products of a membrane cell.

Figure 42. Schematic construction of an electrolysis cell for the production of chloride, sodium hydroxide, and hydrogen using the membrane process (usually bipolar construction)

a) Cathode; b) Anode; c) Membrane; d) Insulation

In the membrane process perfluorinated organic polymers with sulfonyl or carboxyl groups are used exclusively as membranes. The anodes are made of titanium, the cathodes of stainless steel or nickel.

Membrane cells can be in either unipolar or bipolar arrangement [128]. In addition to the main products chlorine and sodium hydroxide, the process yields high-purity hydrogen (> 99.9 %). Drying and removal of oxygen traces can be carried out, if required.

Hydrochloric Acid Electrolysis. Apart from the chlor – alkali electrolysis the electrolysis of hydrochloric acid (in particular for treatment of weak aqueous solutions to enable their disposal) has some economic importance. The cell products (chlorine and hydrogen) are saturated with water vapor and hydrogen chloride corresponding to the partial pressure of 20 % hydrochloric acid at 75 – 85 °C; both product streams are cooled and the remaining chlorine and hydrogen chloride removed from the hydrogen stream by scrubbing with sodium hydroxide. Hydrogen purity is 99.9 %. For further electrolysis processes of some economic importance, see ⟶ Electrochemistry.

4.3. Thermochemical Water Cleavage

In the range T < 2000 K and p = 100 kPa the cleavage of water is described by:

$$H_2O(l) \rightarrow H_2 + 1/2\,O_2 \tag{36}$$

The reaction is endothermic, the thermodynamic standard values are given below [129]:

Reaction enthalpy	$\Delta H^0_{298} = +286.01\ \mathrm{kJ/mol}$
Reaction entropy	$\Delta S^0_{298} = +163.35\ \mathrm{J\,mol^{-1}\,K^{-1}}$
Gibbs free energy	$\Delta G^0_{298} = +237.31\ \mathrm{kJ/mol}$

The equation for the equilibrium constant is as follows:

$$k_{p_{298K}} = \frac{p_{H_2} \times p_{O_2}^{1/2}}{p_{H_2O}} = e^{\frac{\Delta G}{RT}} = 4.2 \times 10^{-78}\sqrt{\mathrm{bar}}$$

The reaction enthalpy, ΔH^0, is fairly temperature independent, as is ΔS^0. As a result, the Gibbs free energy, ΔG^0, decreases substantially with increasing temperature (see Fig. 43). This behavior is typical for highly endothermic reactions.

Figure 43. Gibb's energy, enthalpy, and entropy term of enthalpy ($T\ \Delta S^0$) for cleavage of water in a temperature range of 300 – 1200 K

The energy required for the production of hydrogen can be delivered in the form of chemical energy (see Section Production from Coal and Hydrocarbons), electrical energy (see Section Electrolysis), heat, light or radiation (see Section Other Methods for the Cleavage of Water), or in some combination of these various energy forms. In many cases, the total process consists of a number of steps using chemical, electrochemical, biochemical or photochemical systems. Purely *thermal cleavage* of water occurs only at >2500 K (see Fig. 48). A commercial realization of this reaction is presently not feasible.

In *thermochemical cyclic* processes reaction (36) is carried out in steps with the aid of chemical redox reactions utilizing energy at lower temperature levels. The substances involved in the reaction sequences are recycled. The great advantage compared to electrolysis is, that the low efficiency, resulting from production of electricity, can be avoided and thermal energy is directly converted into chemical energy. If one of the steps involved is an electrolysis step, the process is named a *hybrid cyclic process.*

The possibility of producing hydrogen via multistage cyclic processes was first pointed out by FUNK and REINSTROM [130]. In particular, the possibility of utilizing the heat of high-temperature reactors led to intensive investigations, and a number of processes for laboratory and pilot plants were selected.

4.3.1. *Thermodynamics of Closed Cycles*

Efficiency. A thermochemical cyclic process is subject to many thermodynamical constraints. The maximum attainable efficiency can be calculated according to [130].

$$\eta_{th} = \frac{\Delta H^0}{\Delta G^0} \cdot \frac{T_1 - T_2}{T_1}$$

T_1 is the upper process temperature of the heat source, T_2 the lower process temperature of the heat sink. The factor $\Delta H^0 / \Delta G^0$ is the ratio of the enthalpy to Gibbs free energy for the water cleavage reaction at 298 K and 100 kPa. The factor has a value of 1.2. Table 22 shows calculated efficiencies for T_2 = 298 K.

Table 22. Theoretical thermal efficiency of the thermochemical water cleavage (T_2= 298 K)

T_1, K	η, %	T_1, K	η, %
400	30.7	1000	84.6
600	60.6	1200	90.5
800	75.6	1400	94.8

Thermodynamical considerations show that in the range 300 – 1000 K at least three process stages are necessary to dissociate water thermochemically. At the same time, calculations show that the theoretical efficiency decreases as the number of stages increase [131].

If the heat losses and irreversible chemical reactions that are involved in practical processes are considered, the maximum efficiency attainable amounts to only 50 – 80 % of the theoretical value. However, the overall efficiency reached should still be clearly better than the total overall efficiency of water electrolysis (ca. 30 %).

Entropy-Temperature Diagram. A thermochemical cycle can be displayed graphically in an entropy-temperature diagram. Figure 44 shows this for the MARK 9 process (see Table 23). For simplification it is assumed that the reactions occur at equilibrium conditions (ΔG^0 = 0), that heat losses can be avoided and that no energy is necessary for the transport of reactants. Since the enclosed area corresponds to usable energy, in this case a constant equal to – ΔG^0 = 237.3 kJ/mol, the efficiency of the cyclic process can be determined using other thermodynamic data, e.g., the amount of heat absorbed by the process [132]. The thermodynamics of this process are summarized in [133], [134].

Table 23. Selection of reaction sequences of thermochemical cycles for water cleavage

Designation, Reaction sequence	Number of reactions	Maximum temperature, °C
Metal – bromine cycles		
MARK 1, (de Beni, Euratom)	4	730

The entropy changes at 298 K and 375 K include entropy of formation and vaporization of water. Without those values η is 0.477

4.3.2. *Further Criteria of Thermochemical Cycles*

Further criteria must be considered in order to judge the practicability of theoretical cycles. For example, the reactions should be in the temperature range of 300 – 1000 K; the reaction rate should be sufficiently large; chemistry and kinetics should be known. Furthermore, internal heat compensation should be possible; separation of the reaction products should be feasable using a minimum of energy with a minimum movement of solids. Finally, process and material know-how should be available. A further important condition for the development of a process is the nature of the high-temperature source, e.g., solar concentrator or nuclear high-temperature reactor, and the way this energy is integrated [135], [136].

With the help of computer programs and taking the aforementioned criteria into consideration, several thousand cyclic processes have been suggested. A summary of more than 200 processes can be found in the literature [137-139]. After the feasibility from a technical and process point of view has been investigated, 20 to 30 of these processes remain. These, finally, have been studied in greater detail.

Thermochemical cyclic processes can be categorized according to various aspects, e.g., the number of reaction stages, or the maximum temperature. However, it has become accepted to group them in

families according to the chemicals involved, e.g., iron-chlorine family (Fe, Cl_2, $FeCl_2$, $FeCl_3$), sulfur-halogen family (SO_2, halogen, X_2), copper-chlorine family (Cu, Cl_2, CuCl, $CuCl_2$). In addition, the basic reaction types for the thermochemical cyclic processes can be classified as follows:

Hydrogen formation usually occurs at low or medium temperatures (ambient to 400 °C). Examples are the reactions of metals (Eq. 37) or metal halides (Eq. 38) with acids or the decomposition of hydrides (Eq. 39).

$$2\,Cu + 2\,HCl \rightarrow 2\,CuCl + H_2 \tag{37}$$

$$2\,VCl_2 + 2\,HCl \rightarrow 2\,VCl_3 + H_2 \tag{38}$$

$$2\,HI \rightarrow I_2 + H_2 \tag{39}$$

Oxygen formation takes place at high temperatures (700 – 1000 °C) by oxygen elimination from oxides or oxygen-containing acids. The thermal cleavage of sulfuric acid (Eq. 40), for example, is one of the best-investigated high-temperature process steps:

$$H_2SO_4 \rightarrow H_2O + SO_2 + 1/2\,O_2 \tag{40}$$

Water is introduced into the cycles and allowed to react at various temperature levels. For example, the Deacon reaction (41) is of great interest at *high temperatures*, while at *low temperatures* the reaction of water with bromine or iodine in the presence of sulfur dioxide [Bunsen reaction (42) known since 1853] is particularly important:

$$Cl_2 + H_2O \rightarrow 2\,HCl + 1/2\,O_2 \tag{41}$$

$$X_2 + 2\,H_2O + SO_2 \rightarrow 2\,HX + H_2SO_4 \tag{42}$$

4.3.3. *Thermochemical Cyclic Processes*

Table 23 shows a selection of the various “purely thermochemical” reaction systems described in the literature. The Mark I cycle (Mark cycles, nomenclature JRC, i.e., Joint Research Center, Ispra, Italy) with a four-step mechanism was developed by De Beni in 1969. At the moment the processes belonging to the halogen-sulfur family are invoking the most interest. As an example, the sulfur – iodine process (S – I process) developed by General Atomic Technologies [140] will be described in more detail.

The main reactions are sulfuric acid cleavage (43) at high temperature and the Bunsen reaction (42), a low-temperature step, in which the water cleavage takes place. Hydrogen is converted to a hydrogen halide and oxygen is incorporated in the sulfuric acid

$$2\,H_2O + SO_2 + I_2 \longrightarrow H_2SO_4 + 2\,HI \tag{42}$$

$$H_2SO_4 \longrightarrow H_2O + SO_2 + 1/2\,O_2 \tag{43}$$

$$2\,HI \longrightarrow H_2 + I_2 \tag{44}$$

$$H_2O \longrightarrow H_2 + 1/2\,O_2$$

Using the molar amounts suggested by General Atomic, the Bunsen reaction can be written as:

$$16\,H_2O + 9\,I_2 + SO_2 \longrightarrow \begin{matrix} (H_2SO_4 + 4\,H_2O)^1 \\ (2\,HJ + 10\,H_2O + 8\,I_2)^2 \end{matrix}$$

The excess of iodine leads to a separation of two liquid phases, a lighter phase of aqueous sulfuric acid (1) and a heavier one consisting of hydrogen iodide, water and iodine (2). The process is subdivided into 4 stages as demanded by the necessary basic operations (Fig. 45 A) [140].

Figure 45. A) Material flows in the S – I process according to General Atomic

B) Section III within the S – I process according to General Atomic

In *stage 1* utilizing the Bunsen reaction, the separation of acidic products H_2SO_4 and HI and oxygen occurs. The oxygen is obtained in a mixture with sulfur dioxide from the sulfuric acid decomposition. This gas mixture is passed through the liquid mixture of water, sulfuric acid, iodine and hydrogen iodide. Here sulfur dioxide reacts according to the Bunsen reaction and oxygen remains as the sole gaseous component. The exothermic Bunsen reaction is performed at 120 °C, to make certain, that the products remain in the liquid phase.

Stage 2 represents the drying of sulfuric acid and the sulfur trioxide cleavage. In this stage pure sulfuric acid is produced in a six-stage drying process at medium temperature. In an ensuing evaporation the dry sulfuric acid decomposes into water and sulfur trioxide. After this, sulfur trioxide is catalytically decomposed to sulfur dioxide and oxygen by using high-temperature energy.

In *stage 3* pure hydrogen iodide is extracted from the heavy product phase of the Bunsen reaction and can then be decomposed economically in stage 4 using low-temperature energy. To obtain pure hydrogen iodide for the decomposition in *stage 4*, the heavy product phase of the Bunsen reaction is separated into three pure fractions. Figure 45 shows a simplified process scheme of this stage. The addition of highly concentrated phosphoric acid to the system causes a new phase separation, whereby the heavy phase contains iodine and the light phase hydrogen iodide, water and phosphoric acid. The light phase can be separated off at moderate temperatures. The gaseous product at the head of the separation column is almost pure hydrogen iodide. This is cooled, compressed to 5 MPa and fed to stage 4 in the liquid state.

The bottom product of the column consists of aqueous phosphoric acid. To be able to recycle the phosphoric acid, it must be freed from the excess water. This drying is achieved in a multistage process with vapor compression and consumes a large amount of electrical energy.

The following suggestions have been made to improve stages 2 and 3: power generation by decompression during sulfuric acid drying [141] and optimization of the hydrogen iodide separation with integrated hydrogen formation [142]. This process has been operated on a laboratory scale with a thermal efficiency of 47 %; the aforementioned improvements and optimization of the heat system is said to make an efficiency of 55 % possible.

Several variations of the S – I process are being investigated, e.g., the NIS process with the system Ni – $NiSO_4$ [143], the Mg – S – I cycle with the system MgO – $MgSO_4$ and the C – I – S process using methanol as a reactant as suggested by Japan Atomic Research Institute [144].

4.3.4. *Hybrid Cycle Processes*

Thermochemical – electrochemical hybrid cycle processes are a special form of thermochemical cyclic processes. Here an electrochemical reaction is involved. Hybrid cycle processes can, therefore, usually be designed as two-stage processes.

The *electrochemical* reaction stage is normally run at low temperature, and replaces either the hydrogen producing or the oxygen producing reaction. The necessary energy for the electrochemical reaction must be less than that required for direct electrolysis of water. Table 24 summarizes the thermochemical – electrochemical hybrid cyclic processes.

Table 24. Thermochemical – electrochemical cycles (hybrid cycles)

Designation, reaction sequence	Number of maximum reactions	Temperature, °C
Sulfur – halogen hybrid cycles		
MARK 13 (JRC Ispra)	3	650 – 850
$Br_2 + SO_2 + 2\,H_2O \Rightarrow 2\,HBr + H_2SO_4$		
$H_2SO_4 \Rightarrow H_2O + SO_2 + ½\,O_2$		
$2\,HBr \Rightarrow H_2Br_2$ (electrolytic step)		
Sulfur hybrid cycles		
MARK 11 (Westinghouse Electric Corp., JRC Ispra, General Atomic Technologies)	2	900
$H_2SO_4 \Rightarrow SO_2 + H_2O + ½\,O_2$		
$SO_2 + H_2O \Rightarrow H_2SO_4 + H_2$ (electrolytic step)		
Alkali metal hydride – hybrid cycles		
Me/MeH – hybrid process (F. Behr)	2	700

$H_2O + 2\ Me \Rightarrow 2\ MeH + ½\ O_2$ (electrolytic step)		
$2\ MeH \Rightarrow 2\ Me + H_2$		
Hydrocarbon – hybrid cycles		
Methane – methanol – methanal process (KFA Jülich)	4	950
$CH_4 + H_2O \Rightarrow 3\ H_2 + CO$		
$CO + 2\ H_2 \Rightarrow CH_3OH$		
$CH_3OH \Rightarrow CH_2O + H_2$		
$CH_2O + H_2O \Rightarrow CH_4 + O_2$ (electrolytic step)		

The most important hybrid cyclic process is the so-called Westinghouse cycle (MARK 11, according to the Ispra nomenclature). A large amount of work on this sulfur-family process and some of its steps have been carried out by Los Alamos Scientific Laboratories, Westinghouse Electric Corp., JRC Ispra, KFA Jülich, General Electric and others.

The sulfur hybrid cycle is a simple two-stage cyclic process. The first step is the electrochemical *low-temperature reaction* consisting of the steps (1) cathodic hydrogen formation (Eq. 45) and (2) anodic oxidation of sulfur dioxide to sulfuric acid (Eq. 46).

$$2\,H^+ + 2\,e^- \rightarrow H_2 \tag{45}$$

$$SO_2 + 2\,H_2O \rightarrow H_2SO_4 + 2\,H^+ + 2\,e^- \tag{46}$$

In the *high-temperature reaction* (Eq. 47) the electrically produced sulfuric acid is cleaved into oxygen, water, and sulfur dioxide, the latter is recycled to the anodic process.

$$H_2SO_4 \rightarrow SO_2 + H_2O + 1/2\,O_2 \tag{47}$$

This reaction can be accelerated in the temperature range of 500 – 1000 °C with catalysts (Fe_2O_3, CuO, Pt – TiO_2, Pt – SiO_2). Figure 46 depicts the flow sheet of the MARK 11 process. The stages of developement for the key steps of the process are as follows:

Figure 46. Schematic of the Westinghouse (Mark 11) hybrid sulfuric acid cycle, simplified [145]

a) Electrolysis; b) H_2SO_4 surge tank; c) Acid separator; d) Acid concentrator; e) Acid vaporizer; f) SO_3 decomposition reactor; g) Steam condensor; h) SO_2 condensor

Electrolysis. The desired conditions to be attained for the anodic reactions are:

50 wt % H_2SO_4
SO_2 pressure 100 – 200 kPa
temperature 80 °C

The high anodic overvoltage makes potentials of 680 – 800 mV necessary to obtain current densities of 200 mA/cm^2. To reduce this overvoltage catalysts are being tested. Diffusion of sulfur dioxide from the anode to the cathode and its reduction to sulfur or hydrogen sulfide there must be prevented. This is being attempted by use of H^+-permeable separator membranes (SPE, diaphragms) [146], gas diffusion electrodes as anodes [147], or three-compartment electrolysis cells [148].

Concentration and Cleavage of Sulfuric Acid. The ca. 50 wt % sulfuric acid produced at the anode is first concentrated to maximum 98 wt % in several concentration, temperature and pressure stages, then evaporated at 450 °C and 20 MPa and subsequently decomposed (at 400 – 800 °C into SO_3 – H_2O, at > 800 °C into SO_2 – O_2). Material corrosion problems occur. Silicon carbide and silicon nitride

materials are suitable for the evaporation equipment. For the decomposition of sulfuric acid special alloys with aluminum oxide coating (SS 444, Incolloy 800, Hastelloy G) have been proposed as reactor materials. The sulfur trioxide decomposition has been investigated on a pilot scale at the JRC Ispra in the so-called Christina process. This process has the following special features:

heat provision by hot air
adiabatically-operated cracking reactor with a special construction (see Fig. 47)
downstream heat recovery section.

Figure 47. Design of the reactor for SO_3 decomposition for the Christina process

a) Quartz wool; b) Refractory lining; c) Catalyst container (Incoloy 800); d) Catalyst (iron oxide); e) Thermocouples; f) Pressure vessel (500 °C)

Figure 47 shows the sulfur trioxide cracker which is constructed for a pressure of 2.5 MPa and, with 11 s residence time, gives 95 % conversion with a crack rating of 12 kW. The results of the investigation show that sulfur trioxide cracking (a step of various cycles of the sulfur family), is technically feasible [149].

For the MARK 11 and related processes the theoretical thermal efficiency is 40 – 45 %. At present, an efficiency of 30 % is attainable.

4.4. Other Methods for the Cleavage of Water

All processes mentioned in the following are either still in the laboratory or in the development stage. A review is given by BOCKRIS in [150], where further methods such as *plasmolysis*, i.e., water splitting by high-temperature plasmas, *magnetolysis*, i.e., electrolysis using a potential difference created by magnetic induction, and *magmalysis*, i.e., interaction of steam with fresh basaltic lava in volcanic tubes, are presented.

4.4.1. *Thermolytic and Radiolytic Processes*

Water Thermolysis. The direct thermal cleavage of water, theoretically the simplest method and a priori an ideal process, requires very high temperatures. Figure 48 shows the equilibrium composition of dissociating steam at atmospheric pressure as a function of temperature [151]. The six components present to a significant extent are: H_2O, H_2, O_2, H, O and OH. The degree of water dissociation as a function of temperature is:

2000 K	0.69 mol %
2300 K	2.64 mol %
2700 K	10.35 mol %
3000 K	22.4 mol %
3500 K	57.43 mol %

Figure 48. Molar fraction *a* of species for the dissociation of water at thermodynamic equilibrium as a function of temperature starting from pure steam at a pressure of 10^5 Pa

Appreciable quantities of hydrogen can only be obtained at temperatures significantly above 2000 K.

An economic utilization of this process is difficult, because of the recombination of the reaction products at the high temperatures. Other problems are associated with the recovery or separation of hydrogen from the hot mixture, conservation and recovery of the high-temperature energy and unsolved material problems.

The three different approaches generally considered are:

1. Catalytic thermal decomposition of water on metallic wires at 1600 K, the small degree of decomposition being compensated for by high reaction rates [152].
2. Decomposition of water in the vicinity of a high-temperature-resistant membrane which allows the removal of one of the products with accompanying displacement of thermodynamic equilibrium. Stabilized zirconia or porous ceramic membranes look promising [153].
3. Decomposition of water, followed by rapid quenching of product gases. A quenching speed of 10^5 – 10^6 K/s is required. Special quenching arrangements using cold steam or inert gas jets indicate that up to 90 % of the hydrogen formed can be recovered [154].

The research in this area is aimed at the utilization of high-temperature solar or nuclear energy.

Water Radiolysis. Water can also be cleaved by high-energy radiation. The overall formula for the water radiolysis is:

$$H_2O \rightarrow H, OH, H_2, H_2O_2, OH^-(aq), H^+(aq)$$

The principles of water radiolysis and radiation chemistry in general are described in [155].

Energy from *nuclear sources* is released as high-quantum energy photons (γ-radiation), high-speed particles, either charged (α-particles, protons, and β-radiation), or uncharged (neutrons). The rate of interaction of radiation with a medium, i.e., the rate of energy transfer, is termed linear energy transfer (LET). Pure γ-radiation sources have the smallest, uranium fission fragments the highest value (in water). The radiochemical yield (*G* value) depends on the LET value of the radiation. The *G* value is defined as the number of molecules converted per 100 eV absorbed energy. The $G(H_2)$ value is greatly influenced by the physical state and turbulence in the medium as well as the chemical composition.

The irradiation of water in the liquid state with γ-rays (^{60}Co) gives a $G(H_2)$ yield of 0.45, in the vapor state at 110 °C $G(H_2)$ is 5.2 [156]. With ^{210}Po a $G(H_2)$ value of 1.8 can be attained.

A well-known example of hydrogen formation is the undesired dissociation of the reactor coolant water in nuclear reactors (For safety measures see Section Removal of Hydrogen). Hydrogen production coupled with heat production in nuclear reactors has often been proposed or is the subject of experimental research. The most suitable configuration is seen in the so-called homogeneous reactor [157]. Here normal water serves as a solvent for the nuclear fuel (94 % enriched uranyl sulfate) and as a moderator. Using a $G(H_2)$ value of 1.6 a hydrogen yield of 28.8 kg H_2 per day and Megawatt can be calculated. Only a fraction (ca. 35 %) of the energy is used for the formation of hydrogen, the rest is converted to heat.

Hydrogen, along with higher hydrocarbons, is formed during the radiolysis of methane with a $G(H_2) = 6.4$. The radiolysis of higher aliphatic hydrocarbons yields, along with hydrogen ($G(H_2)$ ethane = 6.6, $G(H_2)$ propane = 8.2), a large number of other products [158].

Another indirect process for the production of hydrogen is considered to be of interest. Carbon monoxide, derived from the radiolysis of carbon dioxide, is converted to hydrogen and carbon dioxide in a subsequent shift reaction; carbon dioxide is then recycled. With a *G* (CO) value of 10 a higher hydrogen yield than obtainable with direct water radiolysis has been calculated [156].

4.4.2. *Photochemical or Photoelectrical Water Cleavage*

Direct photolytic cleavage of a water molecule leads initially to H and OH radicals

$$H_2O \rightarrow H + OH; \quad \Delta H = -457\,kJ/mol$$

The energy necessary corresponds to 1 mol of light quanta with an energy of at least 4.73 eV ($\lambda \leq 262$ nm). This process, however, only occurs in the vacuum UV range at a wavelength of $\lambda \leq 123$ nm, corresponding to a quantum energy of 10 eV [159]. Because of the unavoidable recombination reactions only a small fraction of hydrogen is found in the reaction mixture.

The photolytic cleavage of water with solar radiation is thus not possible; the process must be carried out in stages using several light quanta and with separation of the reactive intermediates. For the development of a process various possible routes can be followed.

Photochemical Systems. It has been known for a long time, that acidic water solutions of transition metal ions such as Cu^{2+}, Fe^{2+}, Eu^{2+}, evolve hydrogen upon irradiation with UV light. The metal ions provide an electron and are thereby oxidized. The quantum yield is relatively high. A cyclic water cleavage with recirculation of the oxidized metal ion back to the initial (reduced) stage is not possible except with Fe^{3+} and Ce^{4+}.

Efforts are presently concentrated on cyclic photo-redox processes with assistance of photosensitizers. The energy terms of such a system for the cleavage of water are shown in Figure 49. Photon energy, after exciting the sensitizer S to S*, is converted into chemical potential by creating the product ions S^+ and R^- (R is referred to as electron relay compound). This light-induced redox reaction is followed by catalytic steps causing water decomposition [160].

Figure 49. Energy term scheme of a light-induced redox reaction coupled with water cleavage [160]

S = sensitizer; R = electron relay compound; Cat^1, Cat^2 = catalysts

Examples for *sensitizers* are: $Ru(bipy)_3^{2+}$, porphyrine derivatives and acridine dyes such as proflavine. As *electron relay compounds* a viologen derivative, e.g., *N*-methyl-*N'*-tetradecylbipyridine, MV^{2+}, salicylate complexes of Eu^{3+}, V^{3+}, and macrocyclic cobalt complexes are used. Suitable catalysts are finely dispersed particles of platinum for formation of hydrogen and colloidal or macrodispersed RuO_2, which assists in the oxygen generation. A generalized overall reaction scheme is given in Figure 50. Difficulties to be overcome are the prevention of side-reactions and attaining a sufficient rate reaction. The former is achieved by using microheterogeneous systems (instead of homogeneous systems), the latter by using bifunctional catalysts, e.g., TiO_2 particles doped with RuO_2, which serve at the same time as support materials for platinum.

Figure 50. Schematic for cyclic water decomposition in a combined catalytic system [161]

A solution containing 10^{-4} mol/L $Ru(bipy)_3^{2+}$ and 2×10^{-3} mol/L MV^{2+} gives a quantum yield in hydrogen (and oxygen) formation of 2 %, with hydrogen yields being 400 mL/h per liter of substrate. This remains constant over at least 40 h [161].

Photoelectrochemical Systems. The photoelectrical water cleavage is based on the absorption of photons in a semiconductor electrode, which is in contact with an electrolyte. One part of the redox process, either oxidation or reduction, takes place on it. The opposing process takes place at the second electrode, thus separating hydrogen and oxygen evolution locally. Figure 51 depicts the energy term scheme of such a photoelectrochemical cell with an n-type semiconductor anode [162]. The steps of the cyclic process can be described as:

1. Absorption of photons creating charge separation by transportation of electrons from the valence band to the conduction band (electron – hole pairs);
2. Abstraction of electrons from the valence band of water, recombination with defect electrons (holes) and oxygen formation;
   Anodic reaction

   $$H_2O - 2e^- \rightarrow 1/2\,O_2 + 2H^+$$

3. Migration of hydrated protons to the cathode;
4. Transfer of electrons from the Fermi niveau of the metal to the protons followed by hydrogen formation.
   Cathodic reaction

   $$2H^+ + 2e^- \rightarrow H_2$$

The choice of the semiconductor is determined by the height of the band gap and its relative energy level. To cleave water, the energy difference between valence band and conduction band must be at least 1.23 eV; in actual fact, it must be much larger. The edge of the conduction band must be sufficiently above the redox Fermi level for water oxidation.

Figure 51. Energy scheme of the photoelectrolysis of water with a $SrTiO_3$ semiconductor electrode

a) Conduction band; b) Valence band

E_F = Fermi energy; E_G = energy gap between valence and conduction band; E_B = “buckling” of the energy level at the boundary layer electrode/electrolyte

With $SrTiO_3$ semiconductor anodes the band levels are at the right height. The band gap, however, is 3.2 eV, so that only the absorption of UV light is effective for charge separation. In case of the TiO_2 semiconductor electrode the conduction band has to be raised by 0.5 V above the hydrogen potential by application of an external voltage. A further complication is the photolytic decomposition of photoactive semiconductor surfaces (photocorrosion) of suitable electrodes [163].

In recent years the *light-induced cleavage* of water in a microheterogeneous semiconductor dispersion has been investigated (see [164]). As semiconductors titanium oxide, titanates, vanadium oxides and cadmium sulfide can be used. The principal mechanism is shown in Figure 52 A. Titanium oxide particles with a diameter of 100 – 500 nm form a transparent dispersion. Locally separated catalyst deposits of platinum and RuO_2 promote the water splitting reactions by reducing protons and forming oxygen; in the case of TiO_2, oxygen normally remains attached to the particle surface in the form of a peroxide.

Figure 52. A) Catalytic water cleavage through band gap excitation of colloidal semiconductors

B) Complete water photolysis scheme through sensitization of a semiconductor particle

(vb = valence band; cb = conduction band, E_F = Fermi energy)

For particles of semiconductors with a large band gap a sensitization mechanism is required. Through light excitation, the sensitizer acquires the chemical potential necessary to promote an electron to the conducting band of the particle from where it is transferred to the platinum catalyst deposited on part of the surface. Following this, the redox reaction leading to water decomposition takes place as described above.

Figure 52 B shows a schematic diagram of the complete process. The sensitization of titanium oxide by forming surface derivatives with transition metal complexes shifts the photochemical excitation range down to 600 nm with a maximum at 480 nm, whereas pure titanium oxide exhibits a band-gap transition absorption only <400 nm [165]. In principle, it should be possible to use such an absorber system and to attain conversion efficiencies of the solar water cleavage up to 15 %.

4.4.3. *Hydrogen Formation in Biological Systems*

The capability of producing molecular hydrogen by biological action is inherent to some microorganisms including *chemotrophs*, i.e., organisms obtaining energy from chemical substrates, and *phototrophs*, i.e., those using light as a source of energy.

The essential step for the biochemical hydrogen formation is the reduction of two protons by the transfer of two electrons. This reaction is brought about by the interaction of appropriate electron-donating enzyme systems. The energy is supplied by any suitable substrate or by a photosystem using visible radiation. The process can take place in free organisms or in immobilized biological systems.

Hydrogen Production from Organic Substrates by Fermentative Bacteria. Some bacteria can be caused to ferment carbohydrates with the development of hydrogen and byproducts such as carbon dioxide. Obligate and facultative anaerobic microorganisms, e.g., various types of *Clostridium*, types of *Ruminococcus, Serratia marcescens*, and *Bacillus polymyxa*, are a means of carrying out this reaction.

In most cases, hydrogen is evolved as the result of anaerobic oxidation of pyruvate, an intermediate in carbohydrate metabolism. Starch, cellulose, and glucose can serve as substrates. The growth conditions of the microorganisms, the pH value of the substrate and the hydrogen partial pressure have a great influence on hydrogen production. Yields range from 0.1 – 2.5 mol H_2 per mole substrate ([166], [167]). The fermentation of carbohydrates is not of any importance from the point of view of hydrogen production. The energy conversion corresponds to ca. 20 % of the energy of combustion of the organic substrates.

Photobiological Production of Hydrogen. The ability to set hydrogen free with the aid of solar energy is found in a number of phototropic organisms such as purple bacteria, green bacteria, cyanobacteria (procaryotes) and several algae (eucaryotes). The majority are aquatic species. An overview is presented in [167].

The mechanisms vary from organism to organism, the main steps, however, are similar to those of the photosynthesis using electron-transporting photosystems connected in series. For example, with green algae, such as the Chlamydomonas types, the mechanism of the photobiological water decomposition follows the scheme depicted in Figure 53.

Figure 53. Photosynthetic electron transport system of hydrogen production [168]

PSI, PSII = photosystems I and II; Y, X = primary electron acceptors of photosystems I and II; Chl = chlorophyll; Q = plastoquinone; Cyt B, Cyt C = Cytochromes B and C; PC = plastocyanine; [Mn] = manganese carrying water oxidizing enzyme; Fd = Ferredoxin

The active reaction centers, together with light-harvesting antenna pigments, are located in the so-called thylakoide membrane of chloroplasts. After irradiation, photosystem II (PS II) extracts electrons from water at a redox potential of + 0.85 V with the assistance of a manganese-containing enzyme. The electron acceptor of PS II delivers electrons to photosystem I through a down-hill electron chain. Photosystem I elevates the electrons to an energy level which allows the reduction of protons to hydrogen (E_0 = – 0.42 V). For the *normal* photosynthetic carbon dioxide fixation the electrons are transferred by means of the NADP – NADPH system at E_0 = – 320 mV, and carbohydrates are generated from carbon dioxide. In the case of *hydrogen formation*, however, the electrons are transferred to the protons by means of the low-molecular mass protein ferredoxin, a powerful reductant, and the enzyme hydrogenase.

Oxygen evolves on the inside and the ferredoxin reduction and hydrogen formation takes place on the outside of the thylakoide membrane (see Fig. 53). Since oxygen diffuses freely through the membrane and deactivates the extremely sensitive hydrogenase, such a system is of little interest for the commercial biophotolysis of water.

Purple bacteria lead to photosynthesis with sulfide, thiosulfate, sulfur or organic compounds as electron donors. Some strains (like *Rhodopseudomonas capsulata*) produce hydrogen and carbon dioxide during irradiation in the presence of organic compounds such as maleate, succinate or especially lactate [169]. Some mutants of *Rh. sphaeroides* may completely oxidize glucose to carbon dioxide and hydrogen. The necessary conditions (low concentrations of N-containing compounds and the absence of molecular nitrogen) indicate that the hydrogen photoproduction is catalyzed by the enzyme nitrogenase. The energy supply is most probably by photosystems I and II and the reduced electron carrier ferredoxin. At the moment, work is proceeding to develop an economical process for the photoproduction of hydrogen from highly polluted waste water using purple bacteria [170].

Cyanobacteria (blue-green algae) represent the most numerous group of phototropic procaryontes. Some of them are able to produce hydrogen. Many filamentous cyanobacteria (e.g., *Anabaena cylindrica* or *Nostoc muscorum*) have special types of cells (heterocysts) in their filaments of vegetative cells. These heterocysts contain the enzymes nitrogenase and hydrogenase, but are deficient in the photosystem II, and are thus not able to cleave water and to produce oxygen. The exceedingly oxygen-sensitive nitrogenase remains active because evolution of oxygen by photosystems I and II is confined to the vegetative cells. The carbohydrate of the vegetative cells provides the reductant for the nitrogen reduction to ammonia, respectively for hydrogen formation. Figure 54 shows schematically the interaction of the metabolism of vegetative cells and heterocysts [171]. The rate of hydrogen production of cyanobacteria is low, yet the feasibility with such systems is considered to be favorable, because hydrogen evolution takes place at ambient conditions and it is expected that suitable mutants can be selected.

Figure 54. Model of hydrogen metabolism by heterocystous blue-green algae

PSI, PSII = Photosystems I and II

Cell-free systems containing chloroplasts, hydrogenases and an electron carrier such as ferredoxin, sometimes immobilized, have been investigated. In a comparatively short period of time a considerable increase in the rate of hydrogen evolution and stability of such systems has been achieved. Latest data show, that this process can go on for ca. 6 h with a rate of hydrogen production amounting to 100 mmol per hour and gram of chlorophyll [172]. Reasons for the stop of the reaction are inhibition of hydrogenases by oxygen, loss of activity of the chloroplasts and autooxidation of electron carriers.

Table 25 shows hydrogen evolution rates by phototropic microorganisms and cell-free systems [167]. The ultimate aim is the development of hydrogen-producing photoreactors containing artificial enzyme systems, but results are not promising at present.

Table 25. Maximum rate of hydrogen evolution by biological systems [167]

Phototropic microorganisms	H_2 evolution per hour and gram dry biomass	
	mL	mmol

Purple bacteria		
Rhodospirillum rubrum	146	6.5
Rhodopseudomonas palustris A	54	2.4
Rh. capsulata SL	130 – 150	5.8 – 6.7
Rh. capsulata B 10	300 – 500	13.4
Rh. capsulata LB 2	178	7.9
Thiocapsa roseopersicina	13	0.6
Cyanobacteria		
Anabaena cylindrica B 629	5 – 40	0.2 – 2.0
An. variabilis	32	1.3
Spirulina platensis	9	0.4
Green algae		
Chlorella vulgaris	4	0.2
Chlamydomonas reinhardii 137 C	45	2.0
Chl. moevussii ICC 97	8	0.4

Cell-free systems*	H_2 evolution per hour and gram chlorophyll		Functioning
	mL	mmol	time, h
Chp + Fd + H_2-ase (*C. pasteur*)	200 – 350	9.0 – 15.5	3.0 – 6.0
Chp + Fd + H_2-ase (*Th. roseopersicina*)	110 – 220	5.0 – 10	3.0 – 6.0
Chp + Fd + H_2-ase (from various sources)	450 – 900	20 – 40	4.0

* Selected basic components: chloroplasts of spinach (Chp), ferredoxin (Fd), hydrogenases of various sources; electron donor H_2O; the experiments were carried out in the presence of O_2-scavengers

4.5. Other Chemical Processes

4.5.1. *Hydrogen from Conversion of Metals*

Alkali and alkaline earth metals react with water or steam according to Equation (48) to yield hydrogen. For hydrogen production in the laboratory the reaction of metals with acids or bases is still used (Eq. 49 and 50).

$$\mathrm{Me + H_2O \rightarrow 1/2\,H_2 + MeOH} \tag{48}$$

$$\mathrm{Zn + 2\,HCl \rightarrow H_2 + ZnCl_2} \tag{49}$$

$$\mathrm{Al + NaOH + 2\,H_2O \rightarrow 3/2\,H_2 + NaAlO(OH)_2} \tag{50}$$

Aluminum, when the surface has been activated by amalgamation, reacts with *hot water* with hydrogen evolution [173]. Zinc, that has been activated with copper, can split *water vapor.*

Hydrogen can be obtained from metal hydrides by heating them as well as by subjecting them to the influence of water (⟶ Hydrides, see Section Hydride Technology). For certain purposes, especially in out-of-door duties (balloons) hydrogen can be produced from lithium hydride, which is light and easily transported (2.8 L H_2 per gram of LiH), from calcium hydride (1.06 L per gram of CaH_2) or from complex hydrides, such as lithium alanate (2.36 L per gram of $LiAlH_4$).

The steam – iron process, which is one of the oldest ways of producing hydrogen, has been subject to reawakened interest. In principle, it is a cyclic process for water cleavage, whereby coal is consumed. The principles of the steam – iron process is shown in Figure 55. In the first step, coal is gasified with steam and air to produce a reducing gas containing carbon monoxide and hydrogen (lean reducing gas). This gas is reacted with iron oxides in the second stage to produce reduced forms of iron oxides. The reduced species are then reoxidized in the third step of the process with water to form the original oxides at the same time producing hydrogen.

Figure 55. Principle of the steam – iron process

a) Iron oxide reduction reaction; b) Water cleavage reaction

Characteristic data for hydrogen production by the steam – iron process in generators, as they were previously used, are:

Table 26.

Periodical operation,	
cycle time	15 – 30 min
reduction time : oxidation time	2 : 1
mean reaction temperature	700 – 900 °C
hydrogen production per generator	250 m^3/h

Continuous production of hydrogen can be achieved if reduction and oxidation of the solids occur in two separate reaction zones and the solid is transported between them. New process suggestions [174] incorporate separated fluidized beds, as can be seen from Figure 56. The reduction gas is produced externally in a coal – steam – air gasification stage (a). The main disadvantage of the steam – iron process is that only 60 % of the reduction potential of the gas is utilized. Power production by both gas and steam turbines and production of process steam may be used to compensate for this.

Figure 56. Process diagram of the continuous hydrogen production by the steam – iron process

Other redox systems for water cleavage which, according to thermodynamics are more efficient than iron, have been suggested, e.g., Zn – ZnO dissolved in lead, 300 – 500 °C, 10 – 20 MPa [175], and Sn – SnO_2 dissolved in tin, ca. 800 °C, 2 MPa [176].

4.5.2. *Hydrogen from Ammonia*

Ammonia is easily thermally decomposed according to the reaction:

$$2\,NH_3 \rightarrow N_2 + 3\,H_2 \quad \Delta H_{298} = +91.86\ \mathrm{kJ/mol}$$

The endothermic reaction is favored by high temperature and low pressure and is accelerated by the presence of nickel or iron catalysts. From one kilogram of ammonia 1.97 m^3 (STP) of hydrogen and 0.66 m^3 (STP) of nitrogen are obtained with an energy requirement amounting to 2.7 MJ without consideration of preheating and evaporation. The residual ammonia concentration is usually lower than 500 ppm (mL/m^3) depending on the equilibrium conditions. Figure 57 shows the corresponding residual ammonia concentrations at 100 kPa with the temperature as parameter. At higher pressure, a higher ammonia content remains in the product gas (e.g., 1000 °C, 3 MPa: NH_3 residual concentration 0.2 vol %).

Figure 57. Residual ammonia concentration corresponding to equilibrium of ammonia formation reaction at 100 kPa

The reaction is conducted commercially at 800 – 900 °C. Standard plants for 1 – 100 m^3 (STP)/h are heated by a separate fuel gas and require water to cool down the product gas. The process can also be conducted autothermally, either by burning a part of the product hydrogen or by preigniting ammonia before the catalyst reactor. This results, however, in a mixture containing less hydrogen (ca. 50 vol %) and containing the product of combustion, water vapor. Usually carbon-free combustion air is used to avoid traces of carbon dioxide and carbon monoxide in the product gas [177].

The hydrogen – nitrogen mixture produced by cracking can be used without further treatment in various areas, e.g., as a protective atmosphere in metal processing (see Section Hydrogen in Metallurgy), or for catalytic oxygen removal from gases. For the recovery of pure hydrogen on a small scale, suitable process steps can be used, e.g., pressure-swing adsorption, diffusion cells (see Section Permeation Processes) or hydride technique (see Section Hydride Technology).

The possibility of hydrogen generation from ammonia leads to consideration of the use of anhydrous liquid ammonia as medium for hydrogen distribution and storage (ammonia as energy carrier, see Section Future Developments). Liquid ammonia contains 17.8 wt % hydrogen, which is 50 % more hydrogen per volume than liquid hydrogen [178].

4.5.3. *Hydrogen from Methanol*

Hydrogen and carbon monoxide can be obtained from the decomposition of methanol by reversal of the synthesis reaction. The endothermic decomposition occurs at temperatures >700 °C without a catalyst, or at 300 – 450 °C on catalysts based on copper – nickel or zinc –chromium alloys. Higher hydrogen yields are obtained by catalytic steam reforming of methanol. The process proceeds via initial methanol decomposition (Eq. 51) followed by a water-gas shift reaction (Eq. 52) as shown in the overall equation (Eq. 53).

$$CH_3OH \longrightarrow CO + 2\,H_2 \qquad \Delta H_{298} = +\,91.7\ \text{kJ/mol} \quad (51)$$

$$CO + H_2O \longrightarrow CO_2 + H_2 \qquad \Delta H_{298} = -\,41.0\ \text{kJ/mol} \quad (52)$$

$$CH_3OH + H_2O \longrightarrow CO_2 + 3\,H_2 \qquad \Delta H_{298} = +\,50.7\ \text{kJ/mol} \quad (53)$$

Information on thermodynamic and kinetic investigations, suitable catalysts and a summary of literature, is given in [179-181].

The reaction is carried out technically at pressures of 0.7 – 3 MPa on CuO – ZnO or CuO –Cr_2O_5 catalysts. The molar ratio of water to methanol will vary from 0.67 to 1.5; excess steam lowers the risk of carbon formation.

Hydrogen production from methanol is used in small to medium-sized plants (some of which are mobile) for the production of 1 – 2 000 m^3 (STP)/h. Purification of the product gas is performed by carbon dioxide scrubbing, pressure-swing adsorption or (especially for small units and high purity), by diffusion through a palladium-silver membrane. Figure 58 shows the schematic of a methanol cracker for 50 m^3 (STP)/h of hydrogen at 1.4 MPa using a PSA purification unit to give 99.9999 % purity. 1.5 m^3 (STP) of hydrogen are produced per kilogram of methanol.

Figure 58. Methanol reformer with pressure swing adsorption purification for the production of 50 m^3 (STP) hydrogen per hour, purity 99.9999 vol % (German Linde)

a) Methanol/water vessel; b) Pump; c) Preheater; d) Reformer; e) Adsorber; f) Heater for heat transfer medium; g) Condensate feedback; h) Cooling water

In Berlin, peak requirements for town gas are covered by methanol cracking. At 1.5 – 20 MPa and ca. 500 °C endothermic methanol reforming reaction and exothermic methanation of the carbon monoxide takes place and a mixture with town gas quality (ca. 50 % H_2, 25 % CH_4, 4 % CO, 20 % CO_2) is obtained. The investment costs are ca. 40 % lower than for a naphtha reformer and the operating costs are also favorable, so that the gas production costs are relatively low, for the small number of days with peak loads [182].

4.5.4. *Hydrogen from Hydrogen Sulfide*

A potential source of hydrogen is hydrogen sulfide which can be obtained in large amounts from scrubbing processes for synthesis and natural gas as well as from desulfurizing processes in refineries. Normally, hydrogen sulfide is converted to elemental sulfur by means of the Claus process or by other oxidizing processes. The recovery of hydrogen and sulfur from waste hydrogen sulfide is an interesting alternative to the manufacture of sulfur alone.

The decomposition reaction is endothermic. At temperatures <1800 K the equilibrium position is thermodynamically unfavorable with respect to hydrogen formation (see Table 27) [183].

Table 27. Calculated equilibria concentration of hydrogen in the decomposition of hydrogen sulfide at 100 kPa [191]

Temperature, K	Equilibrium concentration, mol %
400	1.3×10^{-3}
500	6.1×10^{-3}
600	2.0×10^{-2}
700	4.8×10^{-2}
900	1.9
1073*	7.1
1200	13.1
1400	25.6
1600	37.7

* $K = 1.45\times10^{-2}$.

$$2\,H_2S \rightarrow 2\,H_2 + 1/4\,S_8 \quad \Delta H_{298} = 84.90\,kJ/mol$$

The reaction proceeds readily in the presence of catalysts, e.g., platinum – cobalt (at 1000 °C) [184], disulfides of molybdenum or tungsten (at 800 °C) [185], or other transition metal sulfides, preferably supported on alumina (at 500 – 800 °C) [186].

Development work to increase hydrogen yield and thus to establish commercial use of hydrogen sulfide decomposition, suggests several approaches to avoid thermodynamic restrictions.

Cyclic Processes. Thermodynamically favorable cycles have been suggested, e.g.:

$$H_2S + I_2 \rightarrow 2\,HI + S \tag{54a}$$

(30.0 MPa, 300 K)

$$2\,HI \rightarrow H_2 + I_2 \tag{54b}$$

(600 K, 70 MPa, activated carbon) [187]

$$H_2S + CO \rightarrow H_2 + COS \tag{55a}$$

(470 K, 100 kPa, over COS, NiS)

$$COS \rightarrow CO + S \tag{55b}$$

(1000 K, 100 kPa) [188]

$$aH_2S + H_xC_y \rightarrow yCS_2 + (a+x)/2\,H_2 \tag{56a}$$

$$yCS_2 + ySO_2 \rightarrow yCO_2 + 3\,y/2\,S_2 \tag{56b}$$

$$y/2\,S_2 + yO_2 \rightarrow ySO_2 \tag{56c}$$

(suggested [189])

Equilibrium Displacement. The hydrogen yield can be considerably enhanced by removing either sulfur or hydrogen from the reaction system, thereby shifting the equilibrium. A variety of methods have been considered for the separation of hydrogen from hydrogen sulfide in hot gas streams. Examples are the use of zeolitic, polymeric, metallic, glass and ceramic oxide membranes, pressure-swing

adsorption and thermal diffusion [190]. The hydrogen yields can be increased to twice the equilibrium value by diffusion through Vycor-type glass membranes or a microporous alumina membrane at 1000 °C without degradation of the latter [191]. Laboratory experiments using thermal diffusion columns at moderate to high temperature showed effective separation of hydrogen sulfide decomposition mixtures yielding hydrogen concentration > 90 % [190].

Economic realization of hydrogen sulfide cleavage would provide commercial products and offer the possibility of replacing Claus processes and of recycling hydrogen in refinery hydrodesulfurization processes. However, energy has to be provided at relatively high temperatures. Research is focused on (1) thermal decomposition processes using concentrated solar radiation or (2) photoelectrochemical hydrogen sulfide splitting by irradiation with visible light using colloidal semiconductor electrodes (see Section Photochemical or Photoelectrical Water Cleavage, [192]).

4.5.5. *Hydrogen as Byproduct*

In industrial organic chemistry reasonable amounts of hydrogen are often generated. The amounts are particularly large in the petroleum refineries within the area of catalytic reforming. The most important reactions here are thermal or catalytic cracking, dehydrogenation and oxidation (see Table 28 and Sections Refinery Processes and Petrochemical Processes).

Table 28. Reactions in industrial organic chemistry providing hydrogen

Reaction	Product	Process/Others
Thermal and catalytic cracking		
Hydrocarbons, e.g., $2CH_4 \xrightarrow{\Delta T} C_2H_2 + 3H_2$	acetylene	generally not used anymore. 57% H_2 in crackgas
Hydrocarbons, e.g., $C_2H_6 \xrightarrow{\Delta T} C_2H_4 + H_2$	ethylene	ethane cracking in ethylene plants
Reforming processes in refineries		250 m^3 H_2 per tonne of naphtha
Dehydrogenations		
C_4-fraction: 	butadiene	Dow process, Houdry process
n-Paraffins $CH_3-(CH_2)_nCH_3 \longrightarrow R-CH=CH_2$	higher olefins	UOP process
	styrene	
cyclohexanol–cyclohexanone mixtures	phenol	partly commercially used
		
Oxidations		
$CH_3-CH_2-OH \longrightarrow CH_3-C(=O)H + H_2$	acetaldehyde	Carbide and Carbon Corp.
2-Propanol *sec*-Butanol $\longrightarrow R-C(=O)-CH_3 + H_2$	acetone methylethyl ketone	Standard Oil process IFP process
	cyclohexanone	step in caprolactam production
Miscellaneous reactions		
$2\,CH_3-CH_2-OH \longrightarrow$ $+ H_2O + H_2$	butadiene	Lebedew.process, obsolete, of interest for developing countries
$CH_2(OH)-CH_2-CH_2-CH_2(OH) \longrightarrow$ $+ H_2$	butyrolactone	BASF process, use as solvent
	aniline	Du Pont, development state

4.6. Economic Aspects

At present 77 % of the hydrogen produced is from petrochemicals, 18 % from coal, 4 % by electrolysis of aqueous solutions and at the most 1 % from other sources. A review of the cost structure of hydrogen production will, therefore, pay particular attention to the production methods described in Section Production from Coal and Hydrocarbons. Electrolytic processes are also used under certain economic circumstances and are, therefore, included here and in a prognosis regarding the future supply of industrial hydrogen. For predictions of hydrogen production costs for use as an energy carrier see Chapter Hydrogen Energy.

4.6.1. *Analysis of the Cost Structure*

Hydrogen and hydrogen-rich synthesis gases (in particular H_2 – CO and H_2 – N_2) are either produced directly in plants especially built for that purpose or are recovered as a byproduct. In areas with highly concentrated industrial sites, such as mid-Europe, the ratio of directly to indirectly produced hydrogen is almost 1 : 1 [193]. In the developing countries and in countries with industrial sites widely separated from one another, the fraction of directly produced hydrogen is much larger than the fraction recovered in combined plants.

According to the broad range of feedstocks and the highly developed production processes from each of these feedstocks, an analysis of the cost structure depends on the local conditions, i.e., on the availability and price of the feedstocks. In many countries feedstock prices, such as those used for the direct production of hydrogen, are subject to intervention by the government. Heavy taxation is the rule, but subsidies also occur. Further uncertainties in the cost comparison are the various safety and environmental standards in each country and region which to a lesser extent, however, lead to different hydrogen costs.

For the conditions in the Federal Republic of Germany in 1983 costs for direct production of hydrogen have been calculated [194]. The feedstock prices (Fig. 59) include costs for the feedstock itself and, because in the cases considered the feedstock is also used as fuel, the fuel costs. The rest are capital, material and other energy costs (without the feedstock), personnel and administration costs. They lead to a typical situation, which is also found for other countries in which the feedstock is available at world market prices: Steam reforming of natural gas exhibits the lowest investment costs.

Figure 59. Feedstock and production costs for hydrogen in the Federal Republic of Germany in 1983 in DM/1000 m^3 (STP) H_2; numbers in columns converted to $ by the factor 1.8 (scale on the left)

plain area = costs of feedstock; hatched area = costs of production

The costs of hydrogen production from lignite are almost similarily low, whereby the low feedstock prices for surface-mined coal offsets the high cost of the plant. Whereas the much higher cost of hydrogen from naphtha or heavy fuel oil is a situation found worldwide, the high cost for hydrogen from hard coal is a special case limited to the Federal Republic of Germany, and reflects the special coalmining conditions there. On the world market the cost for coal is usually only slightly higher than the cost for lignite, so that the cost for hydrogen from hard coal should be much less.

The influence of the feedstock price is shown in Figure 60. The dashed lines correspond to the feedstock prices and the resulting hydrogen production costs in the Federal Republic of Germany in 1983 and correspond with the data given in Figure 59.

Figure 60. Production costs for H_2 as a function of feedstock price (Federal Republic of Germany, 1983)

As long as local conditions do not lead to large changes in the capital-dependent costs (ordinate of Fig. 59) the given presentation can be used to give a rough estimate of hydrogen costs and comparisons between various feedstocks by substituting local and actual prices.

The results in Figure 59 and 60 are for a capacity of 100 000 m^3 (STP)/h, which is a very large plant, although not unusual. If the dependence of the hydrogen production cost on plant capacity is required, then the simplified assumption may be made that the *utility costs* are independent of the capacity and that the *investment costs* become relatively less important as long as a large one-train plant can be built. If a modular construction is used, the investment costs do not decrease with increasing plant size. The upper limits for one-train units are ca. 500 m^3 (STP)/h for electrolysis units, ca. 80 000 m^3 (STP)/h for partial oxidation and ca. 100 000 m^3 (STP)/h for steam reforming plants.

Gas purification plants, in particular pressure-swing adsorption plants, are built in modules from ca. 50 000 m^3 (STP)/h upwards, so that a reduction in costs on capacity increase for larger plants is not to

be expected.

For comparison of hydrogen plants with a capacity of ca. 10 m^3 (STP)/h, it makes sense to choose plant types that would not be considered for very large plants, e.g., electrolysis plants or methanol reformers. Figure 61 shows the hydrogen costs as a function of the capacity for Europe in 1983. In addition to these production processes solely for hydrogen, the costs of recovery of hydrogen by means of pressure-swing adsorption from a hydrogen-rich refinery off gas are also given. In this case only the difference in heating value of the refinery gas before and after the hydrogen removal is used for calculation of the feedstock price. For the investment cost the cost of a pressure-swing adsorption unit without any further prepurification can be taken. The range of costs is caused by the additional expenditure for feedstock compression to adsorption pressure. Plants of this type up to a capacity of ca. 100 000 m^3 (STP)/h feed gas have been built.

Figure 61. Production costs for H_2 as a function of the production process and plant capacity [195]

Basis of the cost determination:Investment costs: 1983, Federal Republic of Germany

Natural gas: 8.5 DM/GJ, HHV

Fuel gas: 8.5 DM/GJ, LHV

Power: 0.09 – 0.15 DM/kWh

Naphtha: 650 DM/t

Electrolysis: boundary limits 0.15 – 0.09 DM/kWh

Methanol reforming: boundary limits 525 – 400 DM/t

Steam reforming: boundary limits naphtha – natural gas

Partial oxidation: boundary limits heavy fuel oil 300 DM/t,residues 100 DM/t

A similar curve for U.S. prices of hydrogen was developed in 1978 with forecasts until 1980 [197]. Figure 61 also contains average commercial prices for 5580 m^3 (STP)/h merchant hydrogen which exceed prices for electrolytically produced hydrogen from a plant size of 0.1×10^6 scf/d (see Section Future Developments) on up.

The consequences of part-load operation of the plant also determines the choice of the hydrogen-production process. For a low-capacity rating, processes with low investment costs are preferred, because in this case the product cost depends more or less directly on the necessary feedstock costs and is not influenced by writing off an expensive high-capacity plant. For hydrogen plants in the lower capacity range (ca. 100 – 500 m^3 [STP]/h) electrolysis or methanol reforming is the best choice. For large plants this factor leads to the choice of steam reforming plants using natural gas.

4.6.2. *Prognosis of the Hydrogen Costs*

A short-term prognosis of the hydrogen cost development for industrial use (see Chap. Hydrogen Energy for hydrogen as energy carrier), should be oriented on the present stable supply situation and technically well-proven processes. With the aid of Figure 60 such a prognosis can be made. It shows that in the future hydrogen will still be preferentially produced on a large scale from hydrocarbons. The prognosis can therefore be reduced to investigating price and availability of hydrocarbons in the coming years.

Should it become possible to decouple the price of electrical energy from the price of fossil fuels by using nuclear energy or alternative energy sources and to make electrical energy relatively cheap, the electrolysis process could play an increasingly important role. Figure 62 shows what price changes must occur to assure electrolysis a greater market fraction on a purely economic basis.

Figure 62. Cost prospects for electrolysis as compared to the main process for hydrogen production, steam reforming of natural gas [196]

5. Purification of Hydrogen

In many cases it is necessary to purify technical grade hydrogen by using a variety of processes. These must be chosen in accordance with the final use of the hydrogen to give an economically

satisfactory result. Chapter Purification of Hydrogen gives an overview of the technically important purification steps. They are classified according to the physical and chemical operations involved in the separation processes.

Frequently in industrial-scale plants combinations of the various processes are used. In addition, several alternative processes may be available and may be used depending on the economic situation. In Chapter Production and Chapter Handling of Hydrogen some examples of typical combinations of various gas production and purification processes are given.

5.1. Low-Temperature Processes

The large temperature difference between the boiling point of hydrogen and that of the most frequent impurities is the basis of the low-temperature process (LT process) for the purification of hydrogen. Table 29 shows important properties of hydrogen and the most frequent impurities present in the hydrogen to be treated. The impurities are condensed or sublimated. Low-temperature rectification processes are used, if the impurities are also to be separated from one another. The use of *scrubbing* and *adsorption processes* at low temperatures leads to both high purities and high yields.

Table 29. Boiling points at atmospheric pressure, triple point and critical data of hydrogen and some important components which can be present in raw hydrogen streams

Component	Boiling point at 101.3 kPa		Triple point data		Critical data	
	Temperature, K	°C	Temperature, K	Pressure, kPa	Temperature, K	Pressure, kPa

[a] In more detail in Section Physical Properties.
[b] Upper λ point.
[c] Sublimation

An overview of the basic physical processes which are used for the liquefaction of gases as well as the most important parts of the plants, equipment and machines is given in [198] and [199]. Properties of two- and multi-component mixtures with hydrogen, which are the basis for the calculation of the separation processes given in this chapter, can be seen in Figures 8, 9 and 10 (see Chap. Properties).

Such property data are available in computer data banks of engineering companies. Some data otherwise available is given in [200], [201].

5.1.1. *Condensation Processes*

Simple condensation processes are used, if the difference between the boiling point of hydrogen and the condensing phase, usually hydrocarbons, is sufficiently high. Hydrogen is frequently separated from refinery and dealkylation off-gases, as well as ammonia and methanol synthesis purge gases by the condensation process.

The gas from which hydrogen is to be recovered, usually contains components which are solid at the temperature of the final condensation step. Therefore, a *prepurification* stage is usually required to prevent blockage of heat exchangers, knock-out drums, and piping in the low-temperature section of the plant.

Prepurification and drying remove in particular impurities with a high boiling point such as water, carbon dioxide, and hydrocarbons such as benzene and toluene. These processes (often carried out in stages) are *scrubbing* (e.g., glycol scrubbing for water removal), *adsorption* (e.g., on activated carbon or molecular sieve beds), or *condensation* and *sublimation* of the impurities on reversible regenerator beds or reversing heat exchangers (Revex).

The residual gas mixtures, usually hydrogen – methane, hydrogen – carbon monoxide, or hydrogen – nitrogen mixtures, are cooled down below the condensation temperature. The lower the temperature chosen, the purer is the hydrogen product. In the case of the mixture hydrogen – methane the temperature in the condensator can be lowered below the solidification point of pure methane by the addition of ethane or propane and the hydrogen purity can thereby be increased.

The hydrogen yield depends on the solubility of the hydrogen in the condensate and on the amount of condensate. The yield of hydrogen increases, if the condensate is depressurized in a series of stages and the hydrogen-rich depressurization gas is recycled to the first stage of the compressor. Figure 63 shows the most important ways of generating refrigeration for low-temperature processes in industrial plants.

Figure 63. Principle ways of producing refrigeration for low-temperature hydrogen purification

A) Joule – Thomson expansion of residual gas; B) Hydrogen expansion in a turbine; C) Cold from external refrigeration sources (NH_3, freon, ethylene, etc.); D) Refrigeration cycle with residual gas

If amount and pressure of the impurities, such as methane, carbon monoxide or nitrogen, are large enough (> 3 – 5 vol %), the refrigeration requirements of the plant can be covered by *depressurizing the condensate* in a throttle (Joule – Thomson effect) (Fig. 63 A). Hydrogen is then recovered at high pressure. If the nitrogen or methane content is too low or variable, so that the refrigeration requirements cannot be covered reliably, then hydrogen itself can be expanded, e.g., by producing work in a turbine (Fig. 63 B).

If hydrogen, however, is required under high pressure, *external* refrigeration must be used. This can be done by a conventional external refrigeration plant using ammonia or freon as refrigerant (Fig. 63 C), or using other agents that are suitable for the required temperature level of condensation, in this case, e.g., nitrogen, carbon monoxide or methane (Fig. 63 D). The latter possibility requires the most sophisticated equipment. However, it leads to the greatest plant flexibility with regard to throughput and concentration of the impurities, because the refrigeration load is controlled directly by means of the external refrigeration cycle.

Some examples of processes using condensation alone are:

1. Refinery-gas purification plants, in which refrigeration is by a methane cycle or by decompressing the condensate (Fig. 63 A) with partial depressurization of the product [202].
2. Purification of the off-gas of the toluene dealkylation. Here a two-stage condensation is used for the recovery of pure hydrogen, a C_2, and a methane fraction. The refrigeration is supplied by an ammonia or freon cycle if necessary [203].
3. Recovery of hydrogen from the purge gas of ammonia plants. Here, a one-stage condensation process is sufficient. This process is particularly economic, when argon is recovered as an additional product by fractionation. A nitrogen cycle is used as refrigerant [204], [205].

Further common variations of the condensation process are as follows:

1. Staged decompression of the condensate and recycle of the decompressed gas to increase the hydrogen yield.
2. Partial condensation to fractionate the condensate and, eventually, to avoid the precipitation of solids. In this case the refrigeration can be supplied at a higher temperature, thus saving energy, by using refrigeration cycles which are optimized for the various condensation temperatures (see Fig. 63).

5.1.2. *Condensation and Rectification*

In large-scale plants higher yields and greater product purity are obtained by adding a rectification stage to the condensation step. This is also an advantage, if the impurities must be separated from one another. For the refrigeration many tailored variations exist.

Ethylene Plants. Pure hydrogen is recovered as a byproduct after low-temperature separation of ethane and ethylene from the methane – hydrogen fraction. The demethanizer plays an important part in the economics of the plant because the refrigeration required is at the lowest temperature of the process (⟶ Ethylene – Ethylene Fractionation.).

Coal Liquefaction. Hydrogen is recovered from the off-gas of the Fischer – Tropsch synthesis (operated on a large scale in South Africa by SASOL) by means of low-temperature condensation and rectification processes.

Figure 64 shows the LT separation of the purification unit of the SASOL II plant. In this unit 8675 mol/s (700 000 m^3 [STP]/h) crude gas is separated into 7 fractions, 5 of them in a LT plant. The hydrogen fraction is ca. 3700 mol/s (300 000 m^3 [STP]/h) of 80 % pure H_2 [206]. The crude gas, freed from carbon dioxide, is cooled down close to the hydrate point (i.e., the temperature at which precipitation of solid gas hydrates occurs) [207]. The water condensate is removed and separated into a water and a C_{3+} fraction. The gas phase is dried in an adsorber and cooled down to –35 °C. The condensate produced in this stage is fed to the rectification column g and separated into a C_2 and a C_{3+} fraction. In the following condensation stage a C_2 fraction is recovered by cooling down to ca. –95 °C, in the final stage at –150 °C liquid methane is produced. Methane, the C_2 fraction and the C_3 product are separated in two columns. The gaseous phase in the final knock-out drum e_5, is ca. 80 % pure hydrogen.

Figure 64. Production of H_2 and hydrocarbon fractions from Fischer – Tropsch synthesis off-gas by staged condensation. Separation of the hydrocarbon fractions by low-temperature rectification [206]

a) Adsorber for drying and elimination of traces of long-chain hydrocarbons; b) Heat exchanger; c) Compressor; d) CH_4 recycle compressor; e_1 – e_5) Knock-out drums; f) Pump; g) Column

This purity is suitable for the Fischer – Tropsch synthesis for which the main portion of the hydrogen-rich gas is required. A smaller part of the gas is used for hydrogenation purposes and is purified to 99.5 % using a pressure-swing adsorption process (see Section Pressure-Swing Adsorption (PSA)).

The refrigeration for the LT plant is supplied by an ethylene-propylene cascade and a methane cycle (see Figs. 63 C and 64, compressor d). The refrigeration must compensate for losses to the surroundings, in the heat exchanger and in the liquid product.

The refrigeration is supplied in 7 stages (including methane cycle) between + 9 °C and – 150 °C. The ethylene-propylene cycle has a power requirement of ca. 23 MW.

Low-temperature processes have been proposed for purification of the flash gas which is recovered on the decompression of the coal oil in plants for coal liquefaction by means of hydrogenation. Compared to other alternatives such as scrubbing at low temperature or diffusion separators [208], this concept has shown to be superior with regard to yield, energy requirements, economics and feasibility.

Hydrogen – Carbon Monoxide Recovery. Figure 65 shows a low-temperature process, which simultaneously delivers hydrogen and carbon monoxide of high purity from converted gases and gases from partial oxidation. After leaving a carbon dioxide scrubber, the converted and non-converted crude gas is (1) freed from traces of carbon dioxide and water in an adsorber, (2) cooled in two heat exchangers and in the sump of the carbon monoxide column down to the condensation temperature of carbon monoxide, i.e., ca. 80 K.

Figure 65. H_2 production from synthesis gas by low-temperature condensation and pressure-swing adsorption and production of pure carbon monoxide by rectification (German Linde)

a) Preadsorber; b) Heat exchanger; c) Condensation of CO and CH_4; d) Expansion turbine; e) Joule – Thomson expansion for H_2 recycle; f) CO/CH_4 rectification; g) Compression of expanded gas and PSA gas

Energy and refrigeration is produced by expanding hydrogen in a turbine, thereby expanding down to the inlet pressure of a PSA plant in which hydrogen of 99.9 % end purity can be recovered. The carbon monoxide content in the hydrogen is <0.5 ppm. Liquid carbon monoxide is decompressed stagewise, whereby the major part of the refrigeration requirements of the plant is covered. After warming, the carbon monoxide is fed into a rectification column and purified to about 99 %, the maximum hydrogen impurity thereby being 0.5 %. A plant corresponding to Fig. 65 for a gas throughput of 833 mol/s (67 250 m^3 [STP]/h) synthesis gas has been constructed in two trains. The purge gas of the PSA plant can be recycled to obtain a higher yield of hydrogen and carbon monoxide [209].

Hydrogen – Nitrogen Rectification. Whereas in low-temperature hydrogen purification processes the rectification is employed principally to purify the byproducts, large-scale industrial processes also exist in which hydrogen itself is directly involved in the rectification. In the Braun purifier (part of an Ammonia synthesis process, using steam reforming of light hydrocarbons) (⟶ Ammonia) [210] ammonia synthesis gas is produced by condensing excess nitrogen from the raw gas which contains hydrogen, carbon monoxide, methane and nitrogen. Figure 66 shows the rectification of the hydrogen-nitrogen mixture. The refrigeration is provided by the decompression under production of energy in turbine (b) and by the Joule – Thomson decompression of the remaining gas in a throttle. A similar

process for the production of ammonia synthesis gas from nitrogen rich blast-furnace gas or pit gases has been described [211].

Figure 66. Rectification of an H_2/N_2 mixture and production of NH_3 synthesis gas (molar ratio $H_2 : N_2 = 3 : 1$) in the Braun purifier [210]

a) Heat exchanger; b) Expansion turbine; c) Rectification column; d) Joule – Thomson expansion

Ammonia Purge Gas Separation. A low temperature process for ammonia plant purge gas purification features especially high yields in ammonia recovery and in recovery of hydrogen as a product and for recycle. The application of this process is especially advantageous if the low temperatures occurring in the initial condensation step are utilized in further stages to recover other valuable components such as noble gases and methane [212], [213]. Figure 67 shows the integration of the low-temperature process into the ammonia plant. Several plants have been built for the recovery of liquid argon. If only hydrogen is to be recycled, adsorption is a competing process (see Section Adsorption Processes). Combinations of both processes have also been proposed [209], [214].

Figure 67. Integration of the low-temperature process into an ammonia plant [215]

a) Compressor; b) Recycle compressor; c) NH_3 condensate separator; d) Expansion turbine

5.1.3. *Low-Temperature Absorption Processes*

Absorption processes can yield greater purities than the condensation processes. Absorption processes are operated at higher temperature and thus with lower refrigeration requirements. The low-temperature processes described in this section are physical absorption processes, in which the impurities are condensed and either completely or partially utilized as scrubbing agent (for absorption processes with other scrubbing agents see Section Scrubbing Processes).

Nitrogen Wash. A high-purity hydrogen – nitrogen mixture for ammonia synthesis is obtained by using a liquid nitrogen scrubber (⟶ Ammonia) [216]. This scrubber can not only reduce the catalyst poison carbon monoxide down to a few ppm but the inert gases such as methane and argon can also be removed. The methanation step can thus be avoided.

For modern ammonia processes, in which the synthesis gas is produced at high pressure, the nitrogen scrubber is particularly interesting (see Section Gasification of Coal and Hydrocarbons) At low temperatures around 80 K the system hydrogen – nitrogen is still in the subcritical range, although pure nitrogen under these conditions is already supercritical. The necessary refrigeration for the nitrogen scrubber is produced by decompression of the nitrogen into the hydrogen stream.

Methane Scrubber. For the recovery of pure hydrogen from hydrogen – carbon monoxide mixtures (e.g., from synthesis gas) the use of a methane scrubber is frequently an alternative to the condensation of carbon monoxide. Methane scrubbers attain much higher hydrogen purities, especially with regard to the carbon monoxide content, than would be possible with the carbon monoxide condensation process. Simultaneously, pure carbon monoxide can be produced. Figure 68 shows the most important process stages of a methane scrubber [217].

Figure 68. Plant for the recovery of hydrogen and carbon monoxide from H_2/CO-rich gases using a CH_4 scrubbing process

a) Adsorber for removal of H_2O and CO_2; b) Heat exchanger; c) Scrubbing column for CO with subcooled liquid methane; d) Knock-out drum; e) Separation of loaded wash methane to liquid lean methane (bottom) and pure carbon monoxide (top); f) Pump; g) Expansion turbine; h) Compressor

Crude gas between 1.5 and 4.5 MPa is dried in adsorber (a) and cooled down to ca. 90 K in a heat exchanger (b). The carbon monoxide remaining in the gas phase after condensation is removed down to a few ppm in the scrubber (c) with subcooled liquid methane. The liquid phase from the knock-out drum (d) and from the column bottom after decompression and partial evaporation is fed into the carbon monoxide – methane separation column (e). Here the sump product is pure methane, which is used for scrubbing, whereas a carbon monoxide fraction is obtained as the head product. A carbon monoxide cycle provides the heating and the reflux for the separation column as well as the cooling for the scrubbing column. By decompressing a fraction of the carbon monoxide cycle and generating energy the refrigeration for the heat exchanger is obtained.

In a similar fashion, however without a carbon monoxide – methane separation column, methane scrubbers are used for the purification of refinery off-gas or for the production of pure hydrogen from the purge gas of hydrogenation plants (coal hydrogenation, heavy oil hydrogenation). Similarly, as shown in Figure 68, methane scrubbers combined with adsorption processes can be used for the recovery of pure hydrogen, oxo-synthesis gas and a methane-rich heating gas fraction [213].

Other Scrubbing Agents. Absorption processes at low temperatures are not confined to the aforementioned scrubbing agents. Higher hydrocarbons such as ethylene or propane have also been used. Hydrogen itself can also be used as a scrubbing agent if the product desired is helium. Processes of this kind have been proposed and plants built for the recovery of helium and neon from air separation units and from ammonia purge gas streams [218]. In both cases the noble gases are already preconcentrated by several orders of magnitude compared to their natural abundance.

5.2. Adsorption Processes

5.2.1. *Principles*

Because of the only slight interaction of hydrogen with the usual adsorbing agents in technically important pressure and temperature ranges, adsorption processes are particularly suitable not only for the separation of hydrogen from other gases but also for the separation of impurity traces from hydrogen. For the principles of adsorption see ⟶ Adsorption [219-221].

The adsorbents for hydrogen purification are chosen according to the impurities to be removed. The most common adsorbents are given in Table 30. The gas mixtures are separated by various effects. *Steric effects* prevail if the adsorbent has a uniform and narrow micropore distribution, as is found particularly with the zeolites. *Equilibrium effects* result from different adsorption forces of the gases on the solids, and *kinetic effects* are caused by the different diffusion mobilities of the gases into the pores of the adsorbing agents.

Table 30. Adsorbents for the purification of raw hydrogen

Type	Main adsorption duty
Aluminum oxides	water
Silica gel	water, CO_2, C_{4+}
Activated carbon	CO_2, CH_4, C_{2+}, N_2
Molecular sieve (zeolite)	CH_4, CO, N_2
Carbon molecular sieve	O_2

Although each of these effects is present to a various degree in the adsorbent-gas combinations given in Table 30, the strength of the adsorption forces of the various impurities in the raw hydrogen mixtures can be used to put them in the order shown in Table 31. The sequence shown there may change slightly depending on adsorption agent, partial pressure of the impurity and total gas pressure of the system.

Table 31. Adsorption forces for various components in hydrogen purification

Component	Adsorption forces
Hydrogen	weak
Helium	↓
Oxygen	↓
Argon	↓
Nitrogen	↓
Carbon monoxide	↓
Methane	↓
Carbon dioxide	↓
Ethane	↓
Ethylene	↓
Propane	↓
Isobutane	↓
Propylene	↓
Hydrogen sulfide	↓
Mercaptans	↓
Benzene	↓
Toluene	↓
Ethylbenzene	↓
Styrene	↓
Water	strong

The static equilibrium loading capacity of the adsorbent for a particular component is depicted in the form of an *adsorption isotherm* (loading capacity depending on partial pressure at constant temperature). Adsorption isotherms have typical values for the adsorbents and the components in question and must be determined experimentally. For a number of typical components and some adsorbents these values have been compiled in handbooks and in specification sheets of the various producers.

Figure 69 shows the principal adsorption isotherms of various gases present during hydrogen purification on carbon molecular sieve (active charcoal obtained from coal). There is a characteristic affinity between each particular gas and the solid.

Figure 69. Principle form of equilibrium isotherms of mixtures of hydrogen with nitrogen, carbon monoxide, and methane [222]

Adsorbent material: carbon molecular sieves (activated carbon obtained from coal)

Adsorption is an exothermic process. Desorption, subsequently, is endothermic. In *thermally regenerated adsorbers* the energy necessary for the desorption is obtained by indirect heating of the bed or by using hot purge gas. In *pressure-swing adsorption* the desorption energy is obtained from the energy stored in the adsorption bed (thereby causing a temperature drop) if the pressure or the partial pressure of the components to be desorbed is decreased.

Hydrogen purification takes place in adsorption vessels with fixed beds of adsorbents. Other types, such as trickle beds, adsorption columns with solid circulation, moving beds, or adsorption in ebullating beds, are not used for hydrogen purification on a technical scale.

5.2.2. *Thermally Regenerated Adsorbers*

Thermally regenerated adsorbers are used to remove traces of impurities from hydrogen streams or for selective removal of certain substances which disturb ensuing process steps. The process is often designated as temperature-swing adsorption (TSA).

The adsorbers are usually switched alternately. While one adsorber is in the adsorption stage, the other is regenerated or is held in readiness. Switching usually takes place in a defined sequence, whereby the time for the adsorption step must be chosen shorter than the time calculated for the breakthrough of the impurities. Typical cycle times for these processes are in the range of some hours up to several days.

The process is illustrated in Figures 70 and 71 for the adsorption of carbon dioxide in a hydrogen-rich synthesis gas on a molecular sieve (5 A). As shown in Figure 71, the adsorber becomes loaded to give a local concentration distribution which is indicated by curve a. The maximum adsorbed amount of carbon dioxide in the zone of the equilibrium concentration EZ is given by the equilibrium isotherm for 25 °C at point a in Figure 70.

Figure 70. Adsorption and regeneration of CO_2 and molecular sieve 5 A, pellets

Figure 71. Concentration profiles in an adsorber (MTZ = mass transfer zone; EZ = equilibrium loading zone)

a) End of adsorption; b) End of cocurrent expansion; c) End of regeneration (residual loading); d) Useful cyclic capacity

In most cases regeneration is initiated by depressurizing. This procedure causes a desorption along the 25 °C isotherm to point c. However, because the depressurization is not isothermal, a cooling effect occurs, so that besides the kinetics of the desorption the adsorption conditions at the lower resulting temperature must also be considered. For a so-called cocurrent depressurization the distribution of the concentration in the adsorber is given by curve b of Fig. 71. The equilibrium along the isotherm is attained very slowly. The desorption energy requirements caused by the depressurization lead to a strong cooling of the adsorbent, which in the presence of water vapor can lead to formation of a liquid phase and thus to an irreversible damage of the adsorbent.

The main desorption takes place after the pressure has been lowered (point c in Fig. 70) mainly by increasing the temperature, in this case to 200 °C (point b or, if no previous depressurization took place, point d). The required heat is provided either indirectly by means of inserted heat exchanger coils or by direct heating with a purge gas at higher temperature. After regeneration, the adsorber is cooled to normal operating temperature and pressurized back to normal adsorption pressure.

Applications. Before low-temperature purification and separation can be carried out (see Section Low-Temperature Processes), gas components, which would at low temperatures form solid deposits in the heat exchangers and knock-out drums, must be removed. In synthesis gases from partial oxidation and steam reforming these are in particular water and carbon dioxide, whereas in refinery gases these are usually higher hydrocarbons. In dealkylation and coke oven gases benzene, toluene, and other aromatics must be removed, whereas in sulfur-containing raw gases hydrogen sulfide and carbonyl sulfide are the disturbing components.

If these impurities are present in higher concentrations, the major portion may first be removed by condensation (water and hydrocarbons) and/or scrubbing (CO_2, H_2S and COS). Final purification is then by TSA. A process description of the removal of water and carbon dioxide from a water-rich synthesis gas by TSA is given elsewhere (⟶ Gas Production – The “Classic” Method).

Further applications for TSA in hydrogen purification processes are:

1. Removal of water and ammonia from ammonia purge gases before low-temperature separation.
2. Purification of hydrogen from electrolysis plants. The main impurities are water and oxygen. The latter is converted by means of catalytic oxidation (see Section Catalytic Gas Purification) to water and then removed by condensation and TSA. Hydrogen from the chlor-alkali electrolysis contains also traces of mercury. This can be removed by TSA on a special molecular sieve [223].
3. Removal of various impurities from pure hydrogen before liquefaction. Here the adsorption is carried out at liquid nitrogen temperature. The regeneration is done with pure hydrogen from the recycle gas at ambient temperature (see Chap. Liquefaction of Hydrogen).

5.2.3. *Pressure-Swing Adsorption (PSA)*

Adsorption Mechanisms. Contrary to adsorption with thermal regeneration, pressure-swing adsorption operates at almost constant temperature using partial-pressure differences. However, the small temperature gradients occurring with ad- and desorption contribute considerably to the mechanism of the process. The components to be removed are adsorbed at high system pressure and high partial pressure and are desorbed at low system pressure in accordance with the appropriate equilibrium isotherms of the various impurities (see Fig. 69).

Figure 72 shows, for the example of a hydrogen – carbon monoxide mixture, how carbon monoxide, which is easily adsorbed, reaches the equilibrium loading, a, on the molecular sieve, while pure hydrogen exits the adsorber. When the adsorber capacity is exhausted, the adsorbent must be regenerated. The carbon monoxide loading on the absorbent is reduced by depressurization and hydrogen purging. The difference c is the *available working capacity* of the adsorbent. However, as in the case of TSA, the *actual working capacity* of the total adsorbent is influenced by the presence of mass transfer zones (MTZ) (see Fig. 71). The length of a MTZ is basically determined by (1) the concentration of the component to be removed in the raw gas, (2) by the required product purity, and (3) by kinetic effects.

Figure 72. Adsorption isotherms for CO on molecular sieve

a) Adsorption; b) Desorption; c) Adsorption capacity

The PSA Process. Like the TSA process, the PSA process is cyclic, however, contrary to temperature swings, pressure changes can be carried out more rapidly and allow a shorter adsorption time. Typical cycle times are in the range of 3 to 10 min. Thus, removal of impurities present in high concentrations can be accomplished using moderately sized adsorber vessels. The essential steps carried out in a PSA unit are shown in Figure 73 [224]. Each adsorber is performing a different task, depending on which phase of the complete PSA cycle is regarded. The chronological sequence of all steps constitutes the cycle of one adsorber:

1. Adsorption at the pressure of the raw gas (highest system pressure), hydrogen production (adsorber A);
2. Cocurrent depressurization, provision of gas for pressure equalization and purging (adsorbers F and E);
3. Countercurrent depressurization, production of part of the tail gas (adsorber C);
4. Countercurrent purging (lowest system pressure), production of another part of the tail gas (adsorber D);
5. Countercurrent repressurization (adsorber B).

Figure 73. Six-bed PSA unit. Main flows for adsorption, repressurization, counterflow expansion (dump), counterflow purge, etc. for H_2 production by adsorber A. After termination of this adsorption step, next on-stream adsorber is B, etc.

Adsorber	A	B	C	D	E	F
Function	Adsorption	Repres-surization	Dump	Purge	Depres-surization	Depres-surization
Start pressure, (MPa)	2.8	1.6	0.4	0.2	0.8	2.8
Final pressure, (MPa)	2.8	2.2	0.2	0.2	0.4	2.2

Figure 74 [225] shows the different process stages with respect to the equilibrium loading on the adsorbent. The possibility of continuing the decompression stage into vacuum is also shown. This latter mode of operation is indicated for the enrichment and recovery of the adsorbed component. However, production of concentrated byproducts during the production of pure hydrogen is usually carried out by low-temperature processes and not by the adsorption process.

Figure 74. Theoretical pattern of the status of PSA adsorbers in respect to loading during one adsorption cycle [225]

a) Adsorption; b) Cocurrent depressurization; c) Countercurrent depressurization; d) Purge; e) Depressurization to vacuum; f) Repressurization; g) Equilibrium adsorption isothermal

p_A = adsorption pressure, p = purge gas pressure; p_v = final vacuum obtained

The mode of operation of a PSA can be summarized as follows:

1. Pure hydrogen is produced continuously at adsorption pressure.
2. Tail gas is produced continuously, the pressure, composition, and amount of which fluctuate periodically. These fluctuations are smoothed out by buffer vessels.
3. The efficiency of a PSA is defined by the amount of pure hydrogen produced in relation to the total hydrogen amount present in the crude gas. Depending on the crude gas composition and the degree of technical sophistication utilized, the PSA efficiency ranges between 70 and 90 %.

Technical PSA Plants. The simplest PSA system requires three adsorbers to enable continuous operation. Hydrogen yields of > 80 % can only be attained in systems with more than 4 adsorbers.

Since the size of the adsorber is usually limited because of manufacturing or transport considerations, larger quantities of crude gas can only be treated if several adsorbers are used in the adsorption

phase simultaneously (multi-bed process) [226], [227]. With such schemes PSA plants using 3 to 12 adsorbers can process amounts of crude gas ranging from 100 to more than 100 000 m^3 (STP)/h.

The maximum attainable hydrogen yield is influenced by a number of factors, the most important are:

1. *Composition of the crude gas.*
   For the economical operation of a plant the hydrogen content of the crude gas should be at least 50 %. The maximum hydrogen content is 95 – 99 %. Depending on the total amount of gas, TSA plants may be more suitable for such high-purity raw gases.
   The concentration and nature of impurities with respect to their ad- and desorption behavior determines basically the size of the adsorber which in turn results in higher or lower loss of hydrogen.
2. *Pressure ratio feed gas: purge gas.*
   This influences the size of the adsorber and the extent of the effort necessary for regeneration. At high pressure ratios the yields can be increased by using several pressure equalization steps (plants with more than 4 adsorbers).
3. *Purity requirements and nature of impurities.*
   The hydrogen purity in the PSA plants is usually >99.9 %. Higher purities with respect to those compounds which are poorly adsorbed, such as the inert gases nitrogen, argon, etc., are attainable at the expense of the yield. In spite of this, purities of 99.9999 %, i.e., hydrogen with <1 ppm impurities, can be realized on an industrial scale.
4. *Temperature of the feed gas.*
   High temperatures (>40 °C) result in a lower capacity of the plant, or in a poorer yield. Lower temperatures are therefore favored. Care must be taken, however, to avoid condensation of certain impurities in the regeneration step. For example, liquid or freezing water can damage the adsorbent.

Important developments in the design of large PSA plants were first possible after the introduction of microprocessor control systems. The main problems facing the control system are caused by the speed and the precision required by the short-time cycles. For this reason, modern plants are controlled by microprocessors using a 1-s sequence achieving “real time” control. Beyond this, it is now possible, not only to control the sequence and valves, but also to have a real process control system. This allows a high degree of flexibility for the changing of various process parameters and the indication of disturbances. In particular, the automatic initiation of disturbance strategies in the case of process, pressure and valve failures, e.g., shut-down of an upset adsorber without interrupting hydrogen production, is possible. Very high requirements are placed on the vessels and valves with up to 50 000 cycles (i.e., valve closures) per year. The operational practice has shown, however, that these plants are very reliable, so that they have become standard.

In the past years purification of hydrogen by means of PSA has increased more than any other gas purification process. Figure 75 gives an impression of the breakthrough of this new technology. As can be seen from the number of plants corresponding to the plant capacity, not only the number of plants per year put on stream has increased, but also the amount of hydrogen purified per plant. Plants > 100 000 m^3 (STP)/h inlet gas are not uncommon nowadays.

Figure 75. Worldwide capacity of H_2 gas purification plants with pressure-swing adsorption technology (put into operation from 1966 to 1984)

Applications [224].
Gas Purification in Steam-Reforming Plants (see Section Catalytic Reforming of Hydrocarbons). Other gas purification processes have been more or less completely replaced in this area [228]. For the production of hydrogen and carbon monoxide by steam reforming, PSA in combination with a low-temperature plant can also be economically used. The amount of gas handled by the plants built ranges from 500 – 87 000 m^3 (STP)/h of product gas. These plants use the tail gas produced to fire the reformer. Specially designed control loops and buffer systems lead to a very homogeneous tail-gas flow which is discharged with only small fluctuation in composition and flow, so that a reliable operation of the burners is possible.

Refinery Gases (see Section Refinery Processes). Because of the increasing demand for hydrogen for hydrogenation in refineries the PSA process is used there for hydrogen recovery and production. Refinery gases have a hydrogen content of 60 – 80 % the remainder being higher boiling hydrocarbons (C_6 – C_{10}). These are adsorbed well, but are difficult to desorb which can cause damage to the adsorbent. By choice of suitable adsorbents these difficulties can be avoided. Plants with feed gas capacities up to 100 000 m^3 (STP)/h have already been built. Figure 76 shows the hydrogen purification section in a large refinery in Kuwait.

Figure 76. Production of hydrogen from refinery off-gas. Plant with 12 adsorbers and 2 buffer drums (in the center) for flow and composition equalization

Plant capacity: 100 000 m^3 (STP)/h refinery gas; H_2 content: 80 %; product purity: >99 %; recovery rate: 89.5 %. Erected by German Linde in Kuwait in 1986

Coke Oven Gas (see Section Coke Oven Gas). Coke oven gas purification places the highest demands on the adsorption technology because of the inlet gas composition. Special preadsorbers have been used to remove impurities such as tar, naphthalene and higher sulfur compounds, which have a poor desorption capacity.

Hydrogen-Rich Gases from Various Synthesis Processes. Apart from numerous small plants which operate for example with ammonia or methanol plant purge gas, the coal gasification at SASOL is to be mentioned. 160 000 m^3 (STP)/h of off-gas from the coal gasification, respectively the Fischer – Tropsch synthesis is purified in five PSA plants.

5.3. Catalytic Gas Purification

Four distinct cases for the use of catalytic processes for gas purification can be distinguished:

1. A component of the crude gas is to be catalytically converted to hydrogen, i.e., a secondary hydrogen production process.
2. Impurities in the crude hydrogen are to be catalytically converted into a form which allows them to be more easily removed from the gas by other purification processes (condensation, adsorption).
3. Gas components, which even in traces could be detrimental to the use of the hydrogen, are converted into harmless components with only minor changes in the gas purity.
4. Adsorption processes, in which certain impurities are chemically bound to the adsorbent so strongly that a regeneration during normal operation does not take place.

5.3.1. *Carbon Monoxide Removal*

Hydrogen from synthesis gas may contain up to 50 % carbon monoxide (partial oxidation). Carbon monoxide can be recovered for CO production by a methane scrubber (see Section Low-Temperature Absorption Processes) and used for synthesis, or it can be reacted with water to produce hydrogen and carbon dioxide (water – gas reaction, shift conversion):

$$CO + H_2O \rightarrow H_2 + CO_2$$

The reaction is exothermal. Because of the equilibrium conditions the carbon monoxide conversion is incomplete in adiabatic reactors. For increased carbon monoxide conversion a greater amount of water ($c_{H2O}/c_{CO} > 3$) is necessary. At high carbon monoxide concentration a series of adiabatic reactors with intercooling is used. Isothermal reactors have also been suggested [229]. Depending on the type of catalyst used, three types of conversion may be identified.

Conversion of Sulfur-Containing Gas. Crude gas from partial oxidation or coal gasification, which contains at least 50 ppm hydrogen sulfide, can be converted on metals of group 6, 8, 9, or 10 of the periodic table (exceptions: Cr and Fe) or on mixtures of these metals. The carrier is aluminum oxide, sometimes alkaline compounds are present as a promoter. The metals are totally or partially sulfided, the sulfided form being the most active form. The usual catalysts contain cobalt, molybdenum, and nickel as active components. They can be used at 10 MPa and 250 – 550 °C.

An industrial process with these catalysts was described in Section Gasification of Coal and Hydrocarbons. A detailed description of the kinetics of crude-gas conversion is found in [230], patents in [231].

High-Temperature Shift (HT Conversion). For essentially sulfur-free gases, e.g., the product gas of the steam reformer or the secondary reformer, the well-known carrier-free conversion catalysts on iron oxide – chromium oxide basis can be used, e.g., 74 % Fe_2O_3, 10 % Cr_2O_3, 0.2 % MgO (rest: volatile components). Sulfur up to several hundred ppm can be tolerated although the activity then drops; catalyst poisons are phosphorus, silicon and unsaturated hydrocarbons in the presence of NO_x.

The shift reaction runs almost to equilibrium at space velocities between 3000 and 10 000 m^3 (STP) h^{-1} m^{-3} and pressures up to 7 MPa. The reaction temperatures are in the range 300 – 530 °C [232].

In steam reforming plants usually only one HT conversion stage is installed. To decrease the carbon monoxide concentration further, low-temperature conversion catalysts are used. If the purified synthesis gas in coal gasification plants is to be converted, a series of adiabatic reactors can be used. The last stage of this cascade usually consists of a low-temperature conversion.

Low-Temperature (LT) Conversion. The catalysts for LT conversion are supplied in their oxidized form, the major component of the unreduced catalyst is CuO, usually in a mixture with ZnO. Other components may be Cr_2O_3 and Fe_2O_3 (stabilizers) and Al_2O_3 (carrier) [230], [233]. The temperature range used is 190 – 260 °C; the lower temperature is limited by the dew point of the gas, the upper temperature because of the sensitivity of the copper catalyst to thermal deactivation.

These catalysts are extreme sensitive to sulfur, contents of 0.1 ppm leading to their deactivation, so that a suitably large reactor volume must be used to ensure that any slow deactivation of the catalyst will not cause any premature shut-down of the unit. Very often guard beds are placed before the actual catalyst [234]. For more details on the use of HT and LT shift conversion in steam reforming plants see Section Catalytic Reforming of Hydrocarbons and ⟶ Gas Production.

The thermal stability of copper catalysts can be raised considerably if they are used in a silica-supported form. These supported catalysts are prepared by precipitation from a homogeneous solution and are found to be very active for the water – gas shift reaction [235]. The catalyst can be reduced at a temperature of 450 °C and can be operated between 275 and 400 °C with initial carbon monoxide concentrations up to 10 %. A Fe_2O_3 – Cr_2O_3 catalyst has been prepared in a similar way and also shows improved activity at lower temperature, at the same time the resistance to traces of sulfur and chlorine compounds [236] still being preserved.

Because of considerations of equilibrium, reaction temperature and efficiency of the catalyst, the shift reaction can remove carbon monoxide only down to a remaining concentration of ca. 0.2 – 0.5 vol % in the dry gas. For refinery gases, however, purities <0.1 %, for hydrogenation of fats and oils <10 ppm (mL/m^3) and for ammonia synthesis <1 ppm (mL/m^3) are required (see Chap. Conventional Uses). For these and other purposes a further purification stage is necessary. In many cases this is the methanation step.

5.3.2. *Methanation*

Here, methanation is described as a process for the removal of traces of carbon monoxide or carbon dioxide. For the conversion of large carbon monoxide concentrations to yield substitute natural gas see ⟶ Gas Production – Methanation of Rich Gas.

Especially for ammonia plants the carbon monoxide concentration in the gas must be decreased (see also Fig. 77). This is done by using the reaction

$$CO + 3\,H_2 \rightarrow CH_4 + H_2O$$

The methanation converts carbon monoxide, which is a poison for the ammonia synthesis catalyst, to the inert gas methane. However, losses in hydrogen content (3 mol H_2 per mole of converted carbon monoxide) must be accepted. The design of methanation reactions is described [237].

Figure 77. Removal of CO and CO_2 from ammonia synthesis gas ($3H_2 + N_2$) by selective oxidation (SELECTOXO), CO_2 scrubbing, and methanation

a) Selective oxidation; b) CO_2 scrubber; c) Methanation; d) Regeneration of the scrubbing agent; e) Gas cooling; f) Gas heating

Under typical methanation conditions (high hydrogen partial pressure, low methane and water content) the equilibrium is shifted far to the methane side, so the resulting carbon monoxide concentrations are usually below the detection limit. Nickel oxide, sometimes together with chromium oxide, is used as a catalyst. However, it must be reduced before the start-up. Aluminum oxide or diatomaceous earth is used as carrier. The metallic content of the catalyst is very high (30 – 60 %) compared to the nickel catalyst used for steam reforming.

The following undesired side reactions may occur:

$$CO_2 + 4\,H_2 \rightarrow CH_4 + 2\,H_2O$$

$$2\,CO \rightarrow C + CO_2$$

$$Ni + 4\,CO \rightarrow Ni(CO)_4$$

5.3.3. *Selective Oxidation*

The disadvantage of hydrogen losses and increased inert content in the aforementioned methanation process can be avoided, if carbon monoxide is oxidized to carbon dioxide, because the latter can be readily removed from hydrogen. However, as a side reaction oxidation of hydrogen, which is present in much greater concentration, may occur:

$$2\,CO + O_2 \rightarrow 2\,CO_2$$

$$2\,H_2 + O_2 \rightarrow 2\,H_2O$$

In spite of this, selective oxidation of carbon monoxide can be achieved on a special noble metal catalyst [238-240]. The incorporation of this process stage into the synthesis gas production for ammonia is shown in Figure 77.

The selective oxidation is placed behind the last shift reactor after removal of excess water by condensation. Air, which is taken from the compressed air for the secondary reformer, is used as oxidizing agent. Oxidation takes place at 50 – 70 °C in an adiabatic bed reactor. The temperature increase resulting from the heat of reaction amounts to 10 K per 0.1 mol % carbon monoxide. The carbon monoxide content can be reduced to ca. 100 ppm (mL/m^3) by this method. If the gas is to be used for ammonia synthesis, an additional methanation stage must still be incorporated for final clean-up.

5.3.4. *Catalytic Removal of Sulfur Compounds*

Sulfur compounds are catalyst poisons for hydrogen production and the various syntheses using hydrogen. Desulfurization is achieved in two stages: (1) hydrogenation and (2) hydrogen sulfide removal. Depending on the feed gas, these stages may be carried out separately or simultaneously. In the first step, organic sulfur compounds and carbonyl sulfide are hydrogenated to hydrogen sulfide

$$RCH_2SH + H_2 \rightarrow H_2S + RCH_3$$

$$COS + H_2 \rightarrow H_2S + CO$$

a cobalt – molybdenum contact is normally used as hydrogenation catalyst. If the gas contains a great amount of carbon monoxide, e.g., coke oven gases, the cobalt – molybdenum catalyst must be sulfided in order to avoid methanation of carbon monoxide (see Section Methanation).

Hydrogenation of sulfur compounds is favored by high hydrogen partial pressure and temperatures around 350 °C. After the hydrogenation of the sulfur compounds, the hydrogen sulfide formed can be removed by chemical or physical scrubbing (see Section Scrubbing Processes), if its concentration is > 1 %

For lower concentrations, hydrogen sulfide is absorbed on zinc oxide.

$$ZnO + H_2S \rightarrow ZnS + H_2O$$

Zinc oxide is available in the form of spheres, tablets or extrusions. The average sulfur pick-up until hydrogen sulfide breaks through the bed is ca. 25 % of the stoichiometric amount. The reaction temperatures are 100 – 350 °C (max. 400 °C). Organic sulfur compounds and carbonyl sulfide are partially cracked and absorbed in the zinc oxide bed, so that for natural gases with a low sulfur content the hydrogenation may not be necessary. The final purity after a zinc oxide bed is <1 ppm (mL/m^3) sulfur. The zinc oxide cannot be regenerated in situ but must be replaced.

Other materials used for desulfurization are, e.g., iron hydroxide (a byproduct of aluminum production), iron ore, and other purification agents containing iron oxide or iron hydroxide activated with alkaline compounds [241]. These absorption agents are mainly used for purification of coke oven gas before it is used as town gas. The achievable purity is <2 mg sulfur/m^3 (STP) (ca. 10 ppm [mL/m^3] S as H_2S). Iron- or copper-activated carbon can also be used. The regeneration of these agents with superheated steam is, however, only partially possible.

Chemisorption:

$$2\,Fe(OH)_3 + 3\,H_2S \rightarrow Fe_2S_3 + 6\,H_2O$$

Regeneration:

$$Fe_2S_3 + 3\,H_2O + 3/2\,O_2 \rightarrow 2\,Fe(OH)_3 + 3\,S$$

5.3.5. *Removal of Oxygen*

Hydrogen from coke oven gas and from an electrolysis (contrary to the hydrogen produced from other reducing processes) very often contains oxygen in concentrations up to 1 %. This oxygen is removed in *deoxo* reactors.

$$2\,H_2 + O_2 \rightarrow 2\,H_2O$$

Small levels of platinum and palladium on typical carriers such as α-Al_2O_3, active charcoal, or aluminosilicates provide highly active catalysts for the conversion (e.g., 0.3 % palladium on alumina). The catalyst is active even at ambient temperature, although usually higher temperatures are used.

Because of the strongly exothermic reaction a heat exchanger is installed after the deoxo reactor. The reaction product water is removed by adsorption. An example for the use of this process with prepurified coke oven gas is given in Figure 16.

Another method for oxygen removal is the use of catalytically active non-noble metals, usually copper or nickel, on carriers, e.g., silicon dioxide. These contacts operate at higher temperatures (300 °C) and are less sensitive to impurities such as hydrogen sulfide than are the noble metal catalysts. Both catalytic processes for oxygen removal are very selective, yielding purities of 1 ppm (mL/m^3) oxygen.

5.3.6. *Removal of Nitrogen Oxides*

In gases from coke ovens and coal gasification plants, in particular from entrained-bed gasifiers, traces of nitrogen oxides are present. These must be removed before gas separation in a cryogenic process is possible. Principally, nitrogen oxides can be removed from hydrogen streams by either oxidation or reduction. In the *reduction process* the nitrogen oxides are hydrogenated on sulfided cobalt – molybdenum catalysts, and water and nitrogen are produced. The reaction can be accelerated if small amounts of ammonia are present in the gas. Water and ammonia are removed in downstream scrubbers. The nitrogen produced can usually be neglected for the hydrogen purity.

Oxidative removal of NO takes place with ozone or, particularly selective, with ClO_2. The NO_2 produced is removed by use of scrubbers with alkaline-reducing agents (reduction to nitrogen). Final purities of ca. 0.01 ppm (mL/m^3) NO can be attained.

5.4. Scrubbing Processes

Scrubbing processes are used to purify large quantities of hydrogen. The compounds to be removed are absorbed in the scrubbing liquid. Since this can be done by utilizing either their different solubility in the scrubbing agent or by reaction with the scrubbing agent, the scrubbing processes are subdivided into physical and chemical processes.

5.4.1. *Principles*

For a detailed description of the physical and chemical principles of gas scrubbing see ⟶ Absorption and [242-244].

For selection, design and economics of a physical absorption process the most important factor is the solubility coefficient of a component given as λ (m^3 [STP] bar^{-1} t^{-1}) or λ' (kmol bar^{-1} t^{-1}) [200]. The capacity of an absorbent can be represented by the solubility curve as a function of pressure and temperature. These are shown in Figure 78 for carbon dioxide.

Figure 78. Absorption equilibria of carbon dioxide in various solvents [244]

a) Methanol, –15 °C; b) MDEA (methyl diethanolamine), 75 °C, 3.5 molar; c) MEA (monoethanolamine) 75 °C, 3 molar; d) Hot potassium carbonate, 110 °C; e) TEA (triethanolamine), 75 °C, 2.5 molar; f) NMP (*N*-methylpyrrolidone), 20 °C; g) Propylenecarbonate, 25 °C; h) Selexol (polyethyleneglycol dimethyl ethers)

For physical absorption the capacity at first follows Henry's law (i.e., a linear relationship, curves a, f, g, h), while for chemical absorbents typically a curve, which approaches a saturation value (curves b, c, d, e) is found. Apart from solely physical or solely chemical scrubbing, combined process can be used. Here the scrubbing stages may be separate and operated in series (e.g., crude and fine scrubbing) or a mixture of a physical and a chemical scrubbing agent may be used.

Chemical scrubbing is only suitable for acid gas components such as CO_2, H_2S, COS, and HCN. Physical scrubbing, on the other hand, can also be used for other components such as benzene, and higher hydrocarbons.

The raw gases for hydrogen production, depending on their source, contain several impurities in various concentrations; apart from that, they are at various pressures. For the choice of the optimum scrubbing process, the following factors are important:

1. Type, amount and partial pressure of the component to be removed;
2. Type, amount and total pressure of the gas to be purified;
3. Required final purity, utilization or subsequent process steps for the product gas and the impurities removed;
4. Consumption figures

Physical scrubbing is preferred for large gas quantities at high pressure with high concentrations of impurities to be removed; *chemical scrubbing* is particularly suitable when the absolute amount of the component to be removed is small. It can be used both at atmospheric and at higher pressure. With chemical scrubbing it must also be certain that there is no component in the raw gas, that can react irreversibly with the scrubbing agent. Carbonyl sulfide, for example reacts with MEA (monoethanolamine) to form stable salts. Here the absorbent cannot be regenerated by heat alone, and this leads to a loss of scrubbing agent.

Figure 79 shows how the choice of a suitable scrubbing process can be made for certain limiting parameters (e.g., partial pressure of the substance to be removed in the inlet and the exit gas). An overview of the processes used at present to remove acidic components from gases (synthesis and natural gas), is given in [246].

Figure 79. Examples for the selection of a suitable scrubbing process for CO_2 or CO_2 – H_2S removal with respect to partial pressures in feedgas and product gas, [245]

A) Selection of solvent for CO_2-removal, no H_2S; a) Physical solvent plus amine; b) Physical solvent, physical solvent plus amine or activated hot potassium carbonate; c) Physical solvents, d) Physical solvents or activated hot potassium carbonate; e) Activated hot potassium carbonate or concentrated amine; f) Activated hot potassium carbonate or amine; g) Amine

B) Selection of solvent for simultaneous removal of H_2S and CO_2; a) High loading amines (DEA), Selexol, Rectisol; b) Physical solvents; c) Physical solvents or diglycolamine; d) Activated hot potassium carbonate, Sulfinol, amines; e) Amines, Sulfinol

The most important processes used for purification in hydrogen production are:

1. Carbon dioxide removal from converted steam reformer gases for the production of hydrogen or ammonia synthesis gas. Here the hot potash scrubbers and modifications thereof, often combined with an amine wash, are used (see ⟶ Absorption). In recent times activated MDEA (methyl diethanolamine) wash processes and certain mixed amine processes have been found to have some

economic advantages, however, there still is a tendency to use physical scrubbing processes (Selexol, Sepasolv, etc.) for crude gas purification.

2. For the simultaneous and separate removal of carbon dioxide and hydrogen sulfide from converted or unconverted raw gas from partial oxidation of heavy oil or coal, the Rectisol process has been successful and is used almost exclusively for coal gasification plants.

5.4.2. *Physical Scrubbing (Rectisol Process)*

The Rectisol process (⟶ Gas Production) (jointly developed by Linde and Lurgi) is a physical scrubbing process with methanol as the preferred scrubbing agent. Newer variations use other organic solvents or solvent mixtures (e.g., Rectisol II, [248]). Since the absorption capability of organic solvents increases at lower temperatures and since, in addition, losses of scrubbing agent are smaller, Rectisol processes are usually operated at 200 – 260 K. The solubility of various gases in methanol is given in [200] and [248].

Depending on the process chosen, carbon dioxide and hydrogen sulfide can be recovered together or separately. Usually the simpler plants have a common scrubbing stage. Proper configuration of the main scrubbing and the purification section allows a very high attainable purity (20 – 50 ppm [mL/m^3] CO_2). For special purposes (e.g., methanol synthesis gas), a certain amount of CO_2 can be left in the gas and the fine scrubbing can be used only for the sulfur containing compounds. The disadvantage of the simple process is that a tail gas is obtained which, apart from carbon dioxide, also contains a certain amount of sulfur compounds and other traces (HCN, CO). Such a gas must, therefore, be treated by special processes.

For the production of a sulfur-free carbon dioxide fraction and a hydrogen sulfide fraction suitable for the Claus process, selective Rectisol scrubbing processes are used (⟶ Gas Production). Figure 80 shows a simplified process scheme with process description. Rectisol is very flexible with respect to the attainable purity of the product gas, the pressure range and any possible process variations. In addition, there are no corrosion problems. For ammonia synthesis gas the Rectisol process can be combined advantageously with a low-temperature liquid nitrogen wash (see Section Low-Temperature Processes). Other physical gas scrubbing processes are summarized in Table 32.

Table 32. Physical gas-scrubbing processes

Name	Solvent	Temperature, °C	Licensor
Fluor-Solvent	propylene carbonate	ambient	Fluor
Purisol	*N*-methyl pyrrolidone	ambient	Lurgi
Selexol	polyethyleneglycol dimethylether	0 – 40	Norton
Sepasolv	polyethyleneglycol diisopropylether	0 – 40	BASF

5.4.3. *Chemical Scrubbing Processes*

An example of chemical scrubbing in hydrogen production is the combination Benfield – DEA scrubber (so-called High-Pure Benfield). For the SASOL II and III plants carbon dioxide is removed from the recycle gas of the Fischer –Tropsch synthesis, which in total amounts to 7×10^5 m^3 (STP). After the ensuing low-temperature separation, a gas with 80 % hydrogen is obtained which is fed either to the Synthol synthesis or to a PSA plant. A process scheme is shown in Figure 81.

Figure 81. Flowsheet of a combined Benfield – DEA scrubber (High Pure Benfield) for CO_2 removal from Fischer – Tropsch synthesis recycle gas (SASOL II and III) [250]

a) Absorption column; b) Regeneration column; c) Steam generator; d) Air cooler; e) Water cooler; f) DEA scrubber; g) Heat exchanger; h) Pump

High-Pure Benfield Process. Both scrubbers contain an absorption and a regeneration tower, the latter operating at almost atmospheric pressure. The temperature ranges between 70 and 108 °C in (a) and between 50 and 60 °C in (f). The absorbents are regenerated by indirect heating with steam. The final cooling of the regenerated absorbents takes place in air coolers, the cooling of the purified gas in water coolers. The hot potash scrubber (first stage) lowers the carbon dioxide level below 0.8 vol %, the final DEA scrubber below 80 ppm (mL/m^3). The relatively small carbon dioxide amount from the DEA regeneration column (b_2) is fed to the hot potash regeneration column (b_1) and there, together with the main amount of carbon dioxide, vented into the atmosphere or recovered and used for other purposes.

Table 33 lists some other chemical scrubbers.

Table 33. Industrially important chemical scrubbing processes

Classification	Scrubbing agent	Additives	Trade name, licensor
Amine washes	MEA		
	MEA	not specified	Aminguard (UCC)
	DEA		
	HDEA		Linde
	MDEA		
	DGA		Fluor
	DIPA		Adip
	activated MDEA,	various	Shell BASF
	t-amines	various	UCARSOL (UCC)
Physical – chemical washes	sulfolane, DIPA		Sulfinol (Shell)
	methanol, amine		Amisol (Lurgi)

		amineborate	Catacarb
		borax	Lurgi
		arsenate	Giammarco
Caustic scrubber	NaOH – H_2O	only used for fuel purification, no regeneration	

Oxidative scrubbing processes are sometimes used to remove hydrogen sulfide, e.g., for the purification of coke oven gas or other gases from hydrogen purification plants. Hydrogen sulfide is absorbed and oxidized in the scrubbing agent to form elemental sulfur (⟶ Gas Production). Such processes are:

Stretford process (British Gas Corp.)
Locat process (ARI)
Sulfolin process (Linde)

An overview of the literature on hydrogen sulfide removal from coke oven gas, low-Btu gas, rest gases and natural gas is given in [251], on newer oxidative scrubbing processes in [252]. The scrubbing processes described, however, are unable to remove the so-called “inert components” (noble gases, nitrogen, carbon monoxide, methane). In general, further purification steps on the basis of adsorption and catalysis (see Section Catalytic Gas Purification) as well as low-temperature processes including cryogenic scrubbing with liquid methane (see Section Low-Temperature Processes) are necessary.

5.5. Permeation Processes

For purification of hydrogen and for separation of hydrogen from gas mixtures processes based on the principle of diffusion and permeation through membranes are also suitable. The physical fundamentals of diffusion processes are given in [253] together with a detailed description of diffusion separation methods in [254].

The driving force for gas transport through membranes is the partial pressure of the gases. The permeating flux Q_i (per unit area of surface and time) is given by Equation (57):

$$Q_i = \frac{P_i}{d} \cdot (p_{i2} - p_{i1}) \tag{57}$$

where P_i, the permeation coefficient, is the product of solubility and diffusion coefficients of a gas *i*, p_{i2} and p_{i1} are partial pressures on the high- and the low-pressure sides of the membrane and *d* is the membrane thickness.

To separate various components it is essential to have different permeation coefficients. The separation capability of the membrane is defined by the selectivity α; this is the ratio of the permeation coefficients of the two gases *i* and *j*

$$\alpha = P_i / P_j$$

The fact that the permeation coefficient of hydrogen is much higher than that of other gases is utilized to separate hydrogen by diffusion through metal or polymer membranes.

5.5.1. *Metal Membrane Techniques*

Hydrogen diffuses well and with a high specific permeation rate through membranes consisting of palladium, palladium – silver or palladium – rare earths. Silver – palladium alloys with 23 wt % silver are most suitable. The diffusion rate of hydrogen is highest at a composition close to the maximum solubility of silver in palladium (i.e., ca. 23 wt %); furthermore, material distortion by α – β phase transition in the palladium-hydrogen system is substantially decreased. Optimum operating conditions, i.e., maximum hydrogen throughput and high durability are found at 350 °C and 2 MPa hydrogen pressure. Unsaturated hydrocarbons, halogens and sulfur compounds can lead to rupture of the membrane. The hydrogen suffers a great pressure drop after permeation through the membrane, however, it is particularly pure (impurities and moisture <0.5 ppm [mL/m^3]). Palladium membrane diffusion is discussed in [255].

Portable small-sized hydrogen generators or containerized medium-sized units (the latter are constructed from modular units) can be used for the final purification of hydrogen or for separation from raw gas mixtures, e.g., from methanol or ammonia reforming (see Section Other Chemical Processes). Main parts of a module are the diffusion elements which consist of a number of silver – palladium tubes contained within a cylindrical cell.

Figure 82 shows the cell performance data of commercial pure-hydrogen plants on the basis of diffusion. The raw hydrogen must be fed to the unit at 2.1 MPa, the operating temperature is 300 °C and the average specific energy consumption amounts to ca. 100 W per cubic meter of hydrogen [256]. The process is considered suitable for small- to medium-scale plants. Metal membrane processes have not been adopted for industrial-scale hydrogen purification.

Figure 82. Operating data of hydrogen diffusion cells with Pd-Ag membranes

a) Yields (%, related to input hydrogen amount); b) Hydrogen content in off-gas (vol %); c) Cell output) (% of nominal capacity)

5.5.2. *Polymer Membrane Processes*

New developments in the area of polymer membrane materials also allow their utilization in gas separation technology. The main criteria for suitable separation membranes are high permeation rates together with high selectivity, pressure-resistant membrane structures and chemical as well as thermal stability. State-of-the-art membranes have asymmetric composite layer structures on a woven material support or a composite hollow-fiber membrane structure. The membrane separation stage is built as module; for gas separation module constructions with high packing densities are used, namely spiral-wound modules (> 900 m^2/m^3) and hollowfiber modules (9000 m^2/m^3). An overview is given in [257][258][259]. From the process point of view various module arrangements such as cascades or membrane columns [260] may be used.

Asymmetric composite membranes based on cellulose acetate or polysulfones have a particularly high specific permeability for hydrogen, as do aromatic polyimide membranes; they are used for the industrial scale separation of hydrogen.

The product of Permea, a Monsanto company, is leading in this field. The Perma Prism process [261] uses asymmetrical hollow-fiber membranes of polysulfone with an active siloxane layer (300 – 500 µm outer diameter, 100 – 250 µm inner diameter, effective siloxane separating layer 0.1 µm). Several 10 000 of hollow fibers are connected together in a module, as shown in Figure 83. The fiber bundle is sealed at one end (top) and enclosed in an epoxide mantle at the other end. The modules are installed vertically and have a diameter of 100 or 200 mm and a maximum length of 3 or 6 m. The feed gas, which should be freed of disturbing components (NH_3, H_2S, CH_3OH) by a suitable scrubbing system, is fed into the module near the base. The permeate is removed from the base of the module while the remaining gas is removed from the top. The fibers can be operated with a pressure of up to 15 MPa, whereby the pressure difference may amount to 7 MPa. The operating temperature can be up to 100 °C.

Figure 83. The Prism separator module of Permea

a) Feed stream of mixed gases; b) Permeate gas outlet; c) ASME-coded carbon steel shell; d) Hollow fiber membranes; e) Fiber bundle plug; f) Nonpermeate gas outlet

The stability of the membranes towards impurities is given in % of the corresponding saturation value at 20 °C:

Hydrogen sulfide	up to 10 % of the saturation value
Ammonia	up to 2 % of the saturation value
Water	up to 100 % of the saturation value
Hydrocarbons (C_2 – C_6)	up to 80 % of the saturation value

The degree of purity and the hydrogen recovery rate are determined by the partial pressure difference between the inside and the outside of the hollow fiber, the remaining gas components (i.e., their permeation coefficient) and their partial pressure.

Figure 84 A shows the rate of hydrogen recovery and the obtainable purity as a function of various hydrogen contents in the raw gas. Plots for two feeds (70 % and 40 % H_2) in Figure 84 B show that the ratio of total pressures dramatically affects permeate purity, whereas the effect of further increase in membrane selectivity leads to a plateau above a selectivity factor of 40.

Figure 84. A) Obtainable hydrogen purity vs. hydrogen recovery rate

a) Partial pressure difference 3.52 MPa, H_2 in feed 63 vol %; b) Partial pressure difference 3.52 MPa, H_2 in feed 86 vol %B) Permeate purity with two feeds at different pressure ratios [257] ------- 40 % H_2, 60 % C_1; —— 70 % H_2, 30 % C_1

p_1 = permeate pressure, p_2 = feed gas pressure

Hollow-fiber separators were adopted quickly for commercial applications, more than 160 membrane separation systems have been installed for hydrogen recovery since 1979. Preferred applications are hydrogen recovery from purge gases of ammonia or methanol synthesis loops or from other hydrogen containing gases in the refinery or gas industries. Table 34 gives a survey. Figure 85 shows the

process scheme of a plant for hydrogen recovery from the purge gas of a 545 t/d ammonia plant. 3000 m^3 (STP)/h gas is led through two rows of modules (containing 8 and 4 modules, respectively) at various pressure levels, 90 % of the hydrogen thereby being recovered. This system is especially useful, because a part of the hydrogen can be led back to the synthesis stage at 7 MPa. In a 1000 t/d ammonia plant the recovered hydrogen leads to an additional ammonia production of 40 t/d (ca. 5 %) [262]. However, other valuable components of the gas, such as argon, cannot be recovered in a pure form.

Table 34. Hydrogen containing gases membrane modules can handle

Source of feedgas	Components		Pressure, MPa	Product composition, % H_2	Pretreatment, remarks
	% H_2	others			
Ammonia synthesis purge gas	60	N_2, CH_4, Ar, NH_3	13.0	H_2, 85	water wash, NH_3– conc. <200 ppm (mL/m^3)

6. Liquefaction of Hydrogen

The boiling point of hydrogen is 20.39 K at 101.3 kPa (see Table 2) for n-H_2 and 20.26 K for p-H_2. For more details on the physical properties of n-H_2 and p-H_2 see Chapter Properties.

Like other gases, hydrogen is liquefied because storage and transportation is easier in the condensed state. Further applications of liquid hydrogen are rocket propulsion and scientific experiments, e.g., bubble chambers which are used to produce visible trails of various particles involved in reactions of nuclei and elementary particles. A wide application for liquid hydrogen is predicted in the future hydrogen energy concept (see Chap. Hydrogen Energy).

6.1. Principles of Hydrogen Liquefaction

For the liquefication of gases [263] energy must be removed until the condensation point is reached. This is achieved either by cooling down to low temperatures with external means, such as liquid nitrogen or the magneto-caloric effect, or internally by irreversible or isentropic decompression.

The decompression of hydrogen in a *throttle valve* can only lead to a temperature decrease in a certain range of the Joule – Thomson curve (see Fig. 5). The range which is used technically is from 77 K, the boiling point of liquid nitrogen at 0.1 MPa, down to 25 K. In this range (see Fig. 86) the isenthalpic lines (H = constant) in the T – S diagram are particularly steep. The decompression in the throttle leads to a decrease in temperature or, at the boiling point, to a high degree of liquefaction at a constant temperature. The whole range of the isenthalpic lines, isobars and isochores in the T – S diagram, especially in the two-phase areas and around the triple point is given in [264].

Figure 86. Temperature entropy diagram of n-hydrogen. Illustrated are the liquefaction process and the cooling cycle for a modern liquefaction process, described in Figure 88

Isentropic decompression in turbines or other machines is, generally speaking, possible in all temperature ranges. However, control of the two-phase streams in the neighborhood of the condensation point leads to technical problems. Apart from this, the efficiency of a decompression machine decreases for technical reasons at low temperatures. Therefore, this process is only used for hydrogen above 25 K.

Applying a *magnetic field* to a magnetic substance causes an alteration in the inner structure of the material which in turn leads to a temperature change. In particular, demagnetization of certain metals in the neighborhood of the Curie temperature leads to a maximum temperature decrease. (The Curie temperature is the temperature above which ferro-magnetic material reverts to the paramagnetic state.) Under favorable conditions an isentropic temperature decrease of 1 K/T flux density may be attained.

To obtain greater temperature differences respectively entropy changes, metals or alloys with different Curie temperatures of the components are necessary. For the liquefaction of hydrogen the rare earths (in particular gadolinium), their compounds and alloys are suitable. For a detailed description of the magneto-caloric effect in cryogenic refrigeration processes see [265] and [266].

Hydrogen liquefaction is technically achieved by a series of cyclic processes. The theoretical lowest energy consumption (minimum work) in a reversible Carnot process for the production of liquid p-H_2 (0.1 MPa) from gaseous n – H_2 (25 °C, 0.1 MPa) amounts to 14.23 kJ/g = 3.95 kWh/kg.

In natural hydrogen (n-H_2) at 25 °C the ratio of the nuclear spin isomers o-H_2 and p-H_2 is ca. 0.75 : 0.25. At the boiling point of hydrogen the equilibrium lies almost completely on the side of p-H_2 (see Section Physical Properties). The reaction enthalpy ΔH of the exothermal o – p conversion is in the same range as the heat of evaporation

$$\Delta H \text{ o – p (25 K)} = 1.448 \text{ kJ/mol}$$
$$\Delta H \text{ n – p (25 K)} = 1.086 \text{ kJ/mol}$$
$$\Delta H_{evap} \text{ for p-H}_2 \text{ (25 K)} = 0.811 \text{ kJ/mol}$$
$$\Delta H_{evap} \text{ for n-H}_2 \text{ (25 K)} = 0.828 \text{ kJ/mol}$$

Thus, if the reaction rate of the o – p-conversion is large in comparison to the retention time in storage and transport vessels, a major part of stored liquid n-hydrogen is evaporated even after a few days

[267]. In addition, heat losses through the insulation occur. For this reason, technical hydrogen liquefaction units have o – p conversion reactors incorporated into the process. The o – p conversion takes place on iron oxide gel, iron hydroxide and chromium oxide on alumina catalysts.

The heat of reaction of the o – p conversion must be compensated for by additional refrigeration capacity of the liquefaction unit. In the ideal case the reaction should take place along the equilibrium line (see Fig. 1), because then the lowest reaction enthalpy is involved and the necessary refrigeration is thermodynamically favorable, because it can be delivered at the highest temperature level. In technical plants this ideal case can be simulated by using a cascade of adiabatic or isothermal reactors.

Particular requirements are placed on the purity of the hydrogen to be liquefied, because at liquid hydrogen temperatures all impurities except helium become solid and this would lead to a blockage of the refrigeration unit. Before liquefaction hydrogen of > 99.5 % purity from electrolysis or of 99.99 % purity from a PSA plant is subjected to the following purification steps:

1. Oxygen removal by catalytic conversion in an adiabatic reactor at ambient inlet temperature (electrolysis);
2. Adsorptive drying (electrolysis);
3. Adsorptive removal of remaining impurities nitrogen, methane, argon, carbon monoxide near their condensation temperatures, technically usually at LN_2 temperature, (the adsorbers are regenerated with a fraction of heated hydrogen product) (electrolysis and PSA)

The various purification processes are described in more detail in Chapter Purification of Hydrogen.

6.2. Liquefaction Plants

Up to now, there are only a few hydrogen liquefaction plants operational in the world. The largest, with capacities up to 60 t/d, are in the United States and distribute liquid hydrogen throughout the whole country for general industry purposes and, in particular, as a rocket fuel to the space industry.

Some smaller plants are in operation in Europe, serving also space-transport related purposes, such as in Southern France, or scientific purposes as in the Federal Republic of Germany. The latest plant with a capacity of 5 t/d was erected in the Netherlands in 1988. For the first time European gas customers are to be delivered with liquid hydrogen from this plant. Very large plants have been described. Examples are those envisioned for the hydrogen energy concept with 10 modules, each of a capacity of 250 t/d [268].

Small plants use the Linde – Hampson process for liquefaction of hydrogen [269], [270]. The refrigeration is produced by expansion through a throttle at low temperatures. Precooling with liquid nitrogen (LN_2) at reduced pressure (*bp* 65 K) and relatively high hydrogen pressure (e.g., 12 MPa) is necessary. If liquid hydrogen is used directly, without storage, e.g., for bubble chambers, the o – p conversion becomes unnecessary. The liquefaction unit becomes simpler, although the specific energy consumption of 100 kJ/g (including the LN_2 consumption) still remains high.

The process can also be conducted in two steps. Thereby, the hydrogen is expanded to an intermediate pressure after LN_2 cooling and part is recycled to the second stage of the compressor. In Figure 87 a two-stage Linde-Hampson process is shown.

Figure 87. Hydrogen liquefaction for a two-stage Linde – Hampson process

a) Prepurification, adsorption; b) Heat exchanger; c) Hydrogen compressor; d) Expansion valve

Large-scale plants for hydrogen liquefaction not only utilize Joule – Thomson decompression for the production of the necessary refrigeration but also the decompression of hydrogen in turbines.

Figure 88 shows the process scheme of a hydrogen liquefaction unit without nitrogen precooling [271]. Purified hydrogen is cooled down to ca. 85 K in three heat exchangers against *decompressed* recycle hydrogen. A parallel stream of *pressurized* recycle hydrogen is also cooled down and, in the first turbine, provides part of the necessary refrigeration. In two further decompression stages the refrigeration necessary to cool down hydrogen further and to compensate for the o-p conversion is produced. The liquefaction takes place to ca. 85 % by means of Joule – Thomson decompression of the product hydrogen before entering the last reactor heat exchanger. Completion of the liquefaction and subcooling is accomplished by heat exchange with a small fraction of the recycle hydrogen cooled by Joule – Thomson decompression to lower pressures. The recycle hydrogen quantity is ca. 12 times that of the liquefied hydrogen.

Figure 88. Process flow diagram of a commercial H_2 liquefier without LN_2 precooling (German Linde) [271]

a) Adsorptive and catalytic precleaning; b_1 – b_8) Heat exchangers; c) Adsorbers at LN_2 temperatures; d) o-p conversion reactor; e_1 – e_3) Expansion turbines; f_1 – f_2) Expansion values; g_1) Compressor; g_2) Recycle compressor for H_2 coolant cycle

The *T* – *S* diagram (see Fig. 86) shows the thermodynamic cycle of this hydrogen refrigeration process. In particular, it illustrates the enthalpy differences obtained in the expansion turbines in three temperature ranges. The efficiency and losses during the liquefaction of hydrogen are shown in the energy flux diagram of Figure 89. The specific energy consumption amounts to 60.6 kJ per gram of liquid p-H_2.

Figure 89. Sankey diagram of a commercial H_2 liquefier, revealing the losses of the process (Process according to Figure 88)

b_1 – b_8) Heat exchangers; e_1 – e_3) Expansion turbines

Utilizing the energy produced in the turbines (ϒ = 0.8) a thermodynamic efficiency of 23.7 %, corresponding to a specific consumption of 56.3 kJ per gram of p-H_2 (98 % pure, rest o-H_2), is obtained. The power consumption of the hydrogen recycle compressor can be reduced considerably, if the cooling down to the temperature of liquid nitrogen is carried out with imported LN_2, by a nitrogen refrigeration cascade or by a multi-stage cascade with various refrigerants, e.g., propene, ethylene, methane and nitrogen (see Section Production from Coal and Hydrocarbons). The attainable saving in power must be balanced against the higher cost of the equipment and utilities (LN_2).

In large-scale plants [272] for LH_2 production, the specific energy consumption can be reduced by the following means:

1. Use of LN_2 for precooling,
2. Increased efficiency of compressors and turbines,
3. Decreased insulation losses, and
4. Decreased losses in heat exchangers and reactors.

6.3. Further Developments

Besides the Linde – Hampson process (refrigeration by isenthalpic decompression) and the Claude process (refrigeration by isentropic decompression) a number of other processes, such as the Stirling process, have been suggested for the liquefaction of hydrogen. These have been partially tested in small pilot-scale plants.

In pilot plants for low temperatures between 1 and 4 K, magnetic refrigeration has already been experimentally verified [266], [273], [274]. *Magneto-caloric refrigeration* is achieved in a similar way to thermodynamic processes, such as the isentropic expansion of gas. In the latter process the gas to be liquefied is used as a working medium, whereas in the magneto-caloric process the working medium is a ferromagnetic material (e.g., in the form of a bed through which the hydrogen is flowing).

Carnot, Stirling, Ericson and the Brayton process, which operates between two isentropes and two curves of constant magnetic field strength, can be used for the technical realization of the magneto-caloric process. The strong magnetic fields required (≥10 T) can be produced with the help of superconducting magnets.

The discovery of superconductors with a transition temperature around the boiling point of liquid nitrogen [275] is expected to lead to new developments in this area. Figure 90 shows the concept of a magneto-caloric liquefier operating with helium as a cooling fluid. In the four regenerators (d_1 – d_4) helium is cooled by the magneto-caloric effect. After each stage a partial stream is drawn off for indirect cooling of hydrogen. For the regenerators a common magnetic field coming from a superconducting magnet (8 – 10 T) is provided. The magnet here is still cooled with liquid helium, which must be produced in an additional stage. The projected technical data of such a hydrogen liquefaction unit are listed below:

Duration of magnetocaloric cycle, s	ca. 10
Magnetic flux density, T	ca. 10
Cooling power (at 20.4 K), W	20
Liquefaction rate, L/h	0.7
Liquefaction work, kWh/kg	7.26 (54 % of Carnot)
Power consumption, W	557
Heat losses (at 300 K), W	621
Volume, L	ca. 76
Mass, kg	ca. 166

The low power consumption and the efficiency of 54 % of the Carnot cycle is remarkable [265], [270].

Figure 90. Principle flow diagram of a refrigerator using a magneto-caloric refrigeration cycle. The magnetic regenerators work in a cyclic mode

a) o-p Conversion reactors; b) Heat exchangers; c) Helium cycle compressor; d) Magneto-caloric regenerators

Hydrogen Slush. Liquid – solid hydrogen mixtures (slush) have an increased heat absorption capacity and a higher density than normal boiling liquids. This is an advantageous characteristic in space application, where longer storage times and higher storage densities are important.

Hydrogen slush is produced by a freeze – thaw method, where vapor is continuously withdrawn from a stirred mixture of liquid and solid hydrogen, liquefied and reexpanded into the storage vessel. The latent heat of vaporization is used to freeze the hydrogen. The mixture is then at its triple point (13.8 K, p-H_2, 7 kPa) and has to be protected against air leakage into the system by keeping it under a helium atmosphere.

Solid hydrogen can also be produced by freezing liquid hydrogen at higher pressure on a surface cooled by liquid or gaseous helium. In this case the higher pressure can only be maintained if a temperature stratification can be generated at the surface of the liquid phase [276]. For properties of hydrogen slush see [277].

[Top of Page]

7. Handling of Hydrogen

7.1. Quality Specifications

The hydrogen content of technical hydrogen produced from hydrocarbons is between 97 and 99.5 vol %. The impurities are mainly methane and nitrogen; traces of oxygen, carbon monoxide, carbon dioxide and, depending on the production and purification stages, hydrogen sulfide or ammonia may be present. Hydrogen produced electrolytically is typically >99.5 vol % pure. Impurities in this case are mainly nitrogen, oxygen and water. The mercury content must be limited to max. 0.15×10^{-3} mg/m^3 (for protection of the aluminum material in the downstream purification units [278]).

Hydrogen is available in high and very high purities. The impurities are removed by means of catalytic combustion (oxygen), drying systems (water) as well as by adsorption and diffusion systems. Hydrogen of the utmost purity is needed, for example, in the semiconductor industry. It is purified by diffusion through palladium silver membranes or, more recently, by adsorption and purification on hydride material (purity 7.0, i.e., total impurities <0.1 ppm [mL/m^3]) [279]. Table 35 gives an overview of typical hydrogen purities commercially available.

Table 35. Commercial hydrogen qualities

	Hydrogen “pure”	Liquid

	2.5	3.0	3.8	5.0	5.3	5.6	6.0	hydrogen 6.0

** Total amount of impurities ≤1 ppm (mL/m^3) thereof O_2 ≤0.5 ppm (mL/m^3) and C_nH_m ≤0.1 ppm (mL/m^3).

7.2. Compression and Expansion

Compression. Hydrogen is often needed at high and very high pressures (e.g., for hydrogenations: 5 – 70 MPa, for ammonia synthesis: 8 – 30 MPa). Because of its low molecular mass, however, it is difficult to compress in conventional machines. Special types of compressors have therefore been developed.

For very large amounts of hydrogen, (>50 000 m^3 [STP]), such as are necessary, for example, in the ammonia synthesis, *radial-type* high-pressure *turbo compressors* have become standard. Because the pressure ratio attainable with the hydrogen – nitrogen mixture is relatively low, multistage compressors are used. Leakage problems can be handled by suitable constructions. Extra stages of the synthesis gas compressor are used to recycle hydrogen. In smallercapacity plants (<500 t/d of ammonia) the synthesis gas is compressed in so-called mole pumps. Compressor and motor are thereby enclosed in a steel mantle.

For smaller quantities of gas and high end pressures *piston compressors* are chosen. Depending on the purity requirements placed on the compressed hydrogen three types may be used:

1. *Oil-lubricated* piston compressors for the compression of hydrogen for hydrogenation of oil products.
2. If the small quantities of oil in the hydrogen stream after the oil separator or adsorber cannot be tolerated, *water-lubricated* piston compressors can be used.
3. For the compression of high-purity hydrogen *dry-running* piston compressors are used. The pistons are sealed with specially pivoted and guided PTFE (polytetrafluoroethylene) piston rings or, to avoid friction losses, with labyrinth seals. The leakage gas is fed back to the suction side of the compressor via an active carbon filter in both cases.

Smaller quantities of low-pressure gas requiring moderate compression ratios can be handled with *screw compressors.* This type of compressor is used especially in hydrogen liquefaction plants [280].

Apart from these possibilities, compression can also be achieved by pumping liquid hydrogen to the high pressure desired and then evaporating the liquid. This is used for the LH_2 injection in some hydrogen-fueled vehicle engines. Pressures up to 10 MPa may be obtained [281].

Because of the problems encountered in the compression of hydrogen, methods for the indirect compression have been considered.

In the Donor Solvent process (⟶ Coal Liquefaction – Exxon Donor Solvent Process) [282] for coal hydrogenation, aromatic compounds at a low pressure of 5.0 MPa are first hydrogenated to naphthenic compounds. When the hydrogenated donor liquid is subsequently subjected to the conditions prevailing in coal hydrogenation processes (400 °C, 25 MPa), the hydrogen is set free and used for coal hydrogenation. In this way the amount of hydrogen to be compressed can be reduced considerably.

Decompression. The decompression of hydrogen-rich streams is used to produce refrigeration (see Chap. Liquefaction of Hydrogen) and to recover energy. For high pressure differences and small amounts of gas, piston expansion machines are used; large amounts of gas are handled by turbines. For high pressure drops and large amounts of gas a multistage decompression in turbines is applied. Depending on the power and the utilization of the energy the decompressors drive either generators, brake compressors, recycle compressors or oil brakes.

The power thereby generated can be between 1 and 25×10^3 kW. Since the efficiency of turbines increases with increasing speed, high revolutions are desirable. Turbines with revolutions up to 1×10^5 rpm are built. Depending on their power rating, these turbines may have oil, gas or magnetic bearings.

7.3. Transportation and Distribution

The consumers of hydrogen in the chemical industry (ammonia plants, synthesis gas plants, petrochemical plants) usually produce hydrogen on site. Small- and medium-size consumers can also be supplied with gaseous or liquid hydrogen. The principal possibilities for hydrogen transport within the structure of regional hydrogen logistics are shown in Figure 91 [283]. In any future hydrogen energy concept, transportation of large quantities of hydrogen between regions will be necessary and for this reason, transport in pipelines or liquid hydrogen transport in tankers is under consideration.

Figure 91. Possibilities for hydrogen transport

High-Pressure Hydrogen Transport. Small amounts of hydrogen can be transported in aluminum pressure cans (contents ca. 5 L H_2) and in steel cylinders of various sizes (up to 70 L with H_2 at 20 MPa). Greater amounts of hydrogen are transported in bundles of steel cylinders or in large sized pressure containers, transport being by road or rail. Modern high-pressure transports have a capacity of >4000 m^3 of hydrogen (see Fig. 92) and can be filled in less than 2 h. Oil-lubricated piston compressors are used to compress the gas to 20 MPa; oil and water adsorbers or, for higher purities, special low-temperature adsorbers assure the necessary product purity.

Figure 92. Road transporter for hydrogen with 9 seamless pressure vessels, max. operating pressure 20 MPa (courtesy of Mannesmann Röhren-Werke, Düsseldorf)

Pipelines play a particular role in the transport of large quantities of hydrogen. Table 36 gives information on existing hydrogen pipeline nets. Such nets are run, e.g., in the USA by Air Products, in France by L'Air Liquide and in the Federal Republic of Germany by Chemische Werke Hüls.

Table 36. Existing hydrogen pipelines

		Length, km	Diameter, mm	Operating pressure, MPa	Flow rate capacity
L'Air Liquide, France, Belgium, Netherlands	GH_2	total 300	100	<10	
Sweden	GH_2	6 transfer lines, 6 km	50 – 250	0.01 – 2.8	10 000 m^3/h
Air Products, Houston, USA	GH_2	62	80 – 30	3.5 – 4.0	270×10^6 m^3/a
Chemische Werke Hüls, Rhein-Ruhr-Gebiet, FRG	GH_2	208	100 – 300	2.2	250×10^6 m^3/a
NASA, Florida, USA	LH_2	0.4	150	0.15	

The last-named system was built in 1938. It has a length of 210 km and can transport 250×10^6 m^3 (STP)/a; four suppliers and fourteen users are tied into the system. The experience gained with this pipeline has been used to provide specifications for planning, constructing, operating and maintaining such a system [284]. If natural gas pipelines are to be converted for the transport of hydrogen, it is necessary to consider the suitability of the steel material incorporated under the expected conditions in the presence of hydrogen (pressure level up to 10 MPa; cyclic loads; see Section Materials).

LH_2 Transport. For laboratory uses liquid hydrogen is supplied in transport dewars. Larger quantities are transported in tanks (5000 L) or in tank trailers (3 – 5×10^4 L); in the United States liquid hydrogen is also transported by rail (10^5 L containers). Oversea containers, containing up to 20 000 L of liquid hydrogen are used to supply the European space project Ariane in French Guayana. During the Apollo program, barges with dewars containing up to 900 m^3 of liquid hydrogen were used.

To keep evaporation losses small, the transport vessels have either perlite vacuum insulation or superinsulation (see Section Storage). Figure 93 shows a transport dewar with an additional liquid nitrogen cooling system (evaporation loss <1 %/d) [285].

Figure 93. Laboratory transportation dewar with liquid nitrogen cooling [285]

a) Filling manifold and safety valve; b) Protective shell; c) Liquid hydrogen 21 K; d) Liquid nitrogen 77 K; e) High vacuum; f) Outer shell

Test rigs and transfer lines for liquid hydrogen in the space industry are vacuum-insulated. Piston pumps are suitable to transport small quantities of liquid hydrogen at high pressure, whereas larger quantities require multi-stage radial or axial pumps.

Transportation Costs. The total costs of the transport chain from the hydrogen production to the user site have often been assessed, e.g., in [286], [287]. A number of parameters have to be considered, e.g., to transport the same effective energy through transfer lines hydrogen requires 3.5 – 4 times the amount of compression energy compared with natural gas; the total costs are higher by a factor of 1.3 – 1.6. During the distribution of LH_2 an evaporation loss of 7 – 11 % of the handled quantity must be calculated [288]. A summary of the transport and distribution costs for hydrogen is given [289].

Pipelines are by far the most cost-effective means of transporting gaseous hydrogen over both short as well as long distances. The transport of liquid hydrogen via rail or road is ca. 5 times more expensive, the use of pressure gas cylinders is by far the most expensive (transportation costs are ca. 50 times higher, including the costs of idle equipment, such as gas cylinders and vehicles).

7.4. Storage

Conventional methods for storing hydrogen are well-proven and in service. Depending on the end use, (1) stationary, large-size storage systems, (2) stationary, small-size storage systems, and (3) mobile storage systems can be defined. The latter may be used for transport, for distribution or as a fuel reservoir for prime movers. In all these types of storage systems, hydrogen can be handled in the gaseous (GH_2) or liquid (LH_2) state.

Here methods, such as gas storage under pressure or storage in liquid form, are described. Newer concepts, such as absorption in metals (hydride storage systems) and cryoadsorber storage systems are being developed with a view to future use and are described in Section Hydrogen-Energy Conversion Systems. Table 37 shows various concepts for the storage of hydrogen [289]. For stationary, large-volume systems the optimum storage type is determined by the specific storage capacity *T*. This is the amount of energy storage capacity per unit of the rated charging power (kWh/kW). Specific storage cost estimations including further parameters, e.g., utilization, storage capability, annual cost of facility and subsystems are presented in [290].

Table 37. Overview of processes and possibilities for hydrogen storage

Designation	Compressed hydrogen gas storage			Absorption by metal hydrides		Cryo-adsorption	Liquid hydrogen storage	
	below ground	low pressure	high pressure	e.g., FeTi	e.g., FeTi + MgNi		large volume tank	small volume tank
Operating conditions								
Pressure, MPa	10	1.2	15	0.3 – 5	0.3 – 5	4.2	0.15	0.15
Temperature	ambient	ambient	ambient	0 – 80 °C	80 – 300 °C	77 K	21 K	21 K
Developmental status	commercial	commercial	commercial	development	development	development	commercial	commercial
Range of application	site-dependent seasonal storage	medium capacity	short term or mobile	low to medium capacity	mobile storage	medium capacity	long term high capacity	low capacity

Specific energy storage capacity *T*, kWh/kW	>1000	<30	<30	<3		30 – 45	>50	
Problem areas	availability, diffusion losses		safety	costs, energy transfer	capacity, weight	refrigera-tion source	safety	evaporation losses, safety

Compressed Hydrogen Storage. Pressure storage systems of various sizes and pressure ranges are considered state of the art. The same applies for temporary storage in pipelines ("line packing"). For hydrogen, steel cylinders (up to 70 L at 20 MPa), stationary high pressure vessels (20 m^3 at 20 MPa) or low-pressure spherical vessels (15 000 m^3 at 1.2 – 1.6 MPa) are available. Low-pressure and high-pressure systems are suitable for the storage of day or week supplies.

Underground storage in caverns or aquifers is expected to be possible; storage pressure is up to 16 MPa. Gas losses up to 1 – 3 % of the storage capacity are foreseen [291]. Specific problems due to hydrogen are not anticipated, however, the availability of suitable salt and aquifer formations is limited.

Liquid Hydrogen Storage. The technique for liquid hydrogen storage is well-developed; it is used for the storage, transport, distribution of hydrogen. The vessels are insulated with double-walls (dewars), the space between the inside and outside wall is evacuated and filled with perlite (large vessels) or super-insulation. The rate of loss because of evaporation diminishes with increasing size of the vessel. The losses are defined by the amount of hydrogen evaporated daily. Laboratory vessels have 2 – 3 %, mobile LH_2 transport tanks 1 %, perlite-insulated large-volume vessels <0.1 % losses. For additional reduction of heat leakage the refrigeration available in the boil-off gas can be utilized to cool the insulation. This is achieved by radiation shields thermally connected to the vent tube [292]. Liquid hydrogen vessels are attainable from 100 L cans to large tanks with up to 5000 m^3 volume. Tanks have a high specific storage capacity (ca. 100 kWh/kW) and are suitable as long-term storage systems. Figure 94 shows a tank with a capacity of 2000 m^3 LH_2 installed at the Kennedy Space Flight Center in Florida.

Figure 94. Liquid hydrogen tank with a capacity of 3800 m^3 LH_2 at the Kennedy Space Flight Center in Florida (Photo NASA)

Super-Insulation [293]. A large number of layers of insulation foil is wound around the inside vessel (10 – 60 layers per centimeter). A layer consists of a plastic film, both sides of which have been sputtered with metal, or it is produced from a very fine aluminum foil, which is held apart by spacers of a fabric made from glass filaments or similar material. Energy transport by radiation and conduction of the insulation material is more or less completely interrupted. Values of 5×10^{-6} $Wm^{-1}K^{-1}$ for the heat conductivity can be attained.

Liquid hydrogen storage costs have been estimated [286], [294] as has also been the cost of liquefaction [295]. The energy consumption to liquefy the hydrogen amounts to ca. 1/3 of its lower heating value.

Cost Comparison of Large-Volume Hydrogen Storage. The energy stored in a certain volume of hydrogen, relative to that stored in the same volume of natural gas, is determined by the ratio of the volumetric heating values. Therefore, for otherwise equal systems, the hydrogen storage is more expensive by the factor of ca. 3 than natural gas storage. Studies of the cost situation for various hydrogen storage systems allow the following conclusions [289]:

1. Underground hydrogen storage is the most economic method for all areas of application.
2. Storage in pressure vessels is the most economic above-ground storage system when t <30 h. It is suitable for all short-term storage systems.
3. LH_2 storage is the most economic storage system above ground for t > 30 h.
4. It is not clear, whether the recent concepts for hydrogen storage (metal hydrides or cryo-adsorber systems) (see Section Hydrogen-Energy Conversion Systems) are technically and economically more favorable options.

7.5. Materials

Metallic materials are used during production, transport and storage of hydrogen. The choice of material and its stability in the presence of gaseous, liquid or electrolytically produced hydrogen is therefore of great importance and essential for safe handling of hydrogen in a future hydrogen energy carrier concept [296]. Literature on hydrogen and corrosion is given in [297-299].

Mechanism of Hydrogen Corrosion. The destruction caused by hydrogen in various materials occurs via different mechanisms. The starting point is always the formation of diffusable *atomic* hydrogen. This can be formed by: hydrogen ions, thermal dissociation, or chemisorption and dissociation on active metal surfaces.

The embrittlement induced by formation of atomic hydrogen is well-known in electrolytical processes with gaseous hydrogen. Such defects are mainly encountered if the material surface is activated by plastic deformation, i.e., cyclic stress loading makes a metal more susceptible to hydrogen attack.

Atomic hydrogen is dissolved in the material, whereby it either occupies interstitial sites or accumulates in so-called traps. The reactions which lead to damage are described.

Types of Reaction Leading to Damage. The dissolved diffusable atomic hydrogen can interact with lattice dislocations, lattice defects, internal surfaces, or fields of tensile strain caused by mechanical distortion of the material. At these locations, segregation of the material occurs if the concentration of accumulated hydrogen atoms reaches a critical value. The formation of cracks is thereby initiated or, if microcracks or intergranular fractures are present, crack growth is enhanced (HIC, hydrogen-induced cracking [300]).

Hydrogen can react with the material and form hydrides, e.g., with titanium, niobium, tantalum, molybdenum and tungsten. Because of the fact that enhanced hydride formation takes place in the stress field of cracks, and that hydrides are extremely brittle materials, such elements in alloys can lead to hydrogen embrittlement.

A reaction of hydrogen with carbon contained in ferritic steels and alloys at higher temperature (t > 200 °C) is methane formation. This interaction is called decarburization.

$$Fe_3C + 4\,H \rightarrow 3\,Fe + CH_4$$

Recombination of atomic hydrogen to form molecular hydrogen can also be observed. Both reactions, formation of molecular hydrogen and methane, cause high internal pressures because a gas is trapped inside the material. This can lead to a weakening at the grain boundary, followed by formation of cavities, internal cracks and blistering (fish eyes). Macrocracks can form, if the material is placed under strain.

Effects of Hydrogen Pressure Below Temperatures of 200 °C. At constant pressure no critical reaction is observed. Carbon steel equipment may be used up to a recommended hydrogen pressure of 90.0 MPa. At higher pressure austenitic stainless steel should be used.

In areas where the strain changes periodically, e.g., in transport and storage vessels, changes in the ductility and rate of crack formation have been observed. These changes are influenced by the hydrogen pressure, the temperature, and the frequency of the cycling. The rate of the fissure formation was found to increase by a factor of 3 – 100, depending on the cycle frequency and hydrogen pressure as compared to the same treatment in a hydrogen-free atmosphere [301].

Effects of Hydrogen Pressure at Temperatures Above 200 °C. Hydrogen attack with accompanying decarburization by methane formation occurs at >200 °C and increases rapidly with increasing temperature. It depends on the hydrogen partial pressure and on the type of alloyed steel. Metals such as chromium, molybdenum, tungsten, vanadium, titanium, and niobium reduce the number of nucleation sites by lowering the amount of carbon available for methane formation (carbide stabilizers). The behavior of steel at elevated temperature and hydrogen pressure is summarized in a diagram (see Fig. 95). The original curves “Operating Limits for Steels in Hydrogen Service” were first published by G. A. NELSON in 1949 [302]. They were developed as a result of data from a variety of commercial processes and laboratory experiments. Periodic revisions have been made over the years, the latest being published in [303].

Figure 95. Operating limits for steels in hydrogen service (Nelson diagram)

------- surface decarburization; —— internal decarburization (hydrogen attack)

Below and to the left of the curves for each alloy satisfactory service has been experienced at periods of exposure up to 35 a. The length of time before hydrogen attack can be detected is termed the “incubation period”. It is maintained, that during the incubation period methane pressure builds up in submicroscopic voids; when a void reaches a critical size, microscopically visible fissures appear and the growth rate thereof increases [304]. At temperatures >540 °C the curves are not verified. In this temperature range, high-alloy austenitic steels, which resist decarburization, must be used.

Importance of Foreign Substances. Impurities in hydrogen can inhibit hydrogen attack more or less. Carbon monoxide and water reduce the corrosion activity, oxygen and sulfur dioxide are particularly inhibitive.

Ammonia causes the formation of nitride layers on steel which, when subject to deformation, are ruptured. For this reason, steels used for ammonia synthesis plants must be suitable for both hydrogen and nitride attack. Above 600 °C carbon monoxide causes a carburization of the material. Below 450 °C carbonyl formation can occur which simply removes layers from the iron surface (maximum at P_{CO} 12.5 MPa, 250 °C). Carbon dioxide and hydrogen sulfide are strongly oxidizing at elevated temperatures and can accelerate hydrogen attack. A knowledge of the various forms of hydrogen attack on metallic materials together with the effect of other gas components is especially necessary for high-pressure processes. The choice of material is of particular importance. A summary is given in [305].

Other Hydrogen-Resistant Materials. Other hydrogen-resistant materials are:

Copper and copper alloys up to 400 °C,
Nickel up to 250 °C,
Monel up to 250 °C, and
Inconell up to 540 °C.

For temperatures > 1400 °C the following materials are suitable:

Aluminum oxide
Zirconium oxide
Silicon carbide
Silicon nitride

In general, plastics are not subject to attack by hydrogen at ambient temperatures. At higher temperature, the following materials are suitable:

Poly(vinyl chloride) and polyethylene (up to ca. 60 °C)
Polychloroprene and polyisobutylene (up to ca. 100 °C)
Poly(tetrafluoroethylene) (up to ca. 250 °C)

Materials for Liquid Hydrogen (LH_2). At the low temperatures of liquid hydrogen none of the corrosion inducing mechanisms can take place. Material problems are reduced to the effect on mechanical properties.

Mechanical design with metallic and non-metallic materials at low temperatures as well as construction and assembly methods are compiled [306]. The alteration of material properties, such as elastic moduli, fracture behavior, plasticity and fatigue behavior, is handled in detail.

Only a few metals and alloys commercially available are used in cryogenic engineering. Aluminum alloys are widely used, because of their relative cheapness, good weldability and high toughness. Austenitic steels (300 series) are also widely used, because they retain high strength and good ductility down to low temperature. For cryogenic work, low carbon grades are preferred to prevent the precipitation of chromium carbides during welding. Other materials used are nickel-iron, titanium, and copper alloys.

Selection and use of organic polymer materials at cryogenic temperatures is described [307]. Modification of epoxy or polyester resins by incorporation of inert fillers or the use of fiber-reinforced composite materials and laminated structures using glass, Kevlar, carbon, etc., give materials satisfactory for cryogenic service.

7.6. Removal of Hydrogen

The removal of hydrogen may become necessary, if it develops in an uncontrolled manner and causes a safety risk or if a gas must be purified from traces of hydrogen. Normally, hydrogen, which cannot be utilized, is burned, often together with other disturbing compounds and combustible waste gases. If the hydrogen content is not sufficient to support a flame, the so-called flameless combustion with oxygen at 700 – 800 °C with external heating can be used. This technique is applied particularly often for fume incinerators.

More common is the catalytic combustion on noble metal catalysts (Deoxo) or mixed-oxide catalysts, e.g., CuO – MnO_2 (Hopcalite or similar) [308]; catalytic recombinators are also used in maintenance-free lead accumulators.

Further, hydrogen can be removed by absorption and oxidation, e.g., by aqueous solutions of silver or palladium salts or sodium chlorate. As a solid “absorbent” copper oxide or nickel oxide is suitable.

$$CuO + H_2 \rightarrow Cu + H_2O$$

$$NiO + H_2 \rightarrow Ni + H_2O$$

For the removal of 1 m^3 (STP) of hydrogen ca. 3 kg of copper in the form of copper oxide are necessary; the reaction takes place at 200 °C, the catalyst can be regenerated with air. For production of high-purity inert gases hydrogen traces can also be removed by means of hydride material (see Section New Developments for Hydrogen Storage).

Hydrogen Mitigation in the Nuclear Industry. During normal operation in water-moderated nuclear reactors small amounts of hydrogen are permanently formed by radiolytic splitting of water. In the waste-gas system of nuclear plants recombinators are installed. These are usually commercially available catalytic or thermal units.

In case of a nuclear core uncovery accident, hydrogen may be produced by several mechanisms. (1) The exothermic zircalloy – steam reaction occurs once the fuel cladding reaches temperatures of 900 – 1200 °C. (2) A considerable degree of radiolytic water cleavage inevitably accompanies an emergency core cooling procedure (with a great amount of water) for a period of time after the loss of the coolant has occurred. Hazard analysis studies provide values of 5000 m^3 of hydrogen formed within 50 d [309]. It is believed that at Three Miles Island hydrogen amounting to 8 vol % (370 kg) accumulated in the atmosphere of the containment building. (3) The interaction of a hypothetical core melt with concrete or other materials present within a containment system is considered to be an additional source of hydrogen.

Various specific countermeasures to cope with the hydrogen problem have been studied; some of them have been proposed for installation or have been implemented [310]. First of all, hydrogen distribution is to be prevented by subcompartmented containments, and devices to reduce hydrogen concentration should be provided (fans, recombinators, etc.). In case of massive hydrogen release in small containments, blanketing with nitrogen is foreseen, whereas in intermediate containments the use of water fogs or Halon 1301 injection is recommended to mitigate hydrogen deflagration risk and inhibit combustion. Finally, deliberate ignition and controlled burning systems are reported to be effective hydrogen controlling measures, whereby catalytic and spark hydrogen igniters can be used [311], [312].

7.7. Safety Aspects

General. Hydrogen forms inflammable and explosive mixtures with oxygen and other elements. Basic ignition and explosion data are given in Section Ignition and Detonation Performance. For comprehensive compilations of safety characteristics and hazards on handling hydrogen see [313-315].

The envisaged large-scale introduction of hydrogen as an energy carrier requires a comparative evaluation of safety aspects with regard to other fuels. Comparative data for methane (representing natural gas), propane and gasoline are shown in Table 10. Volumetric leakage of hydrogen gas will be 1.3 – 2.8 times as large as gaseous methane leakage and approximately four times that of air under the same conditions (rule: “air-proof is not hydrogen-proof”).

Released hydrogen disperses rapidly by turbulent convection, drift and buoyancy, thus shortening the hazard duration. The prompt dispersion, however, favors the formation of gas mixtures within the wide flammability and detonability limits; the lower limit is the vital one in most applications and is comparable to that of other fuels.

The minimum energy for ignition of hydrogen – air mixtures is extremely low. However, the ignition energy inherent in virtually every source is more than sufficient for ignition of any other fuel – air mixture as well. Ignition by catalytic action is also possible.

Fire Hazards. Hydrogen flames are nearly invisible in daylight. Fire-detection technology is summarized in [316]. Hydrogen fires last only one fifth to one tenth of the time of hydrocarbon fires, and the fire damage is less severe because of several characteristics:

1. high burning rate resulting from rapid mixing and high propagation velocity,
2. high buoyant velocity,
3. high rate of vapor generation of liquid hydrogen

Although the maximum flame temperature is not much different from that of other fuels, the thermal energy radiated from the flame is only a part of that of a natural gas flame. Smoke inhalation, one of the major causes of injury and, therefore, a main parameter of fire damage, is considered less serious in the case of hydrogen because the sole combustion product is water vapor.

Explosive Hazards. High laminar burning velocity as well as the high laminar flame speed of hydrogen makes the transition to turbulent flame speeds exceeding 800 m/s up to several km/s easy. Hence, hydrogen is more sensitive to *deflagration to detonation transition* (DDT) than hydrocarbons. Studies on DDT mechanisms are referred to in [317]. Hydrogen has by far the widest limits of detonability; detonation of stoichiometric hydrogen – air mixtures in confined spaces will produce a static pressure rise of ca. 15 : 1. If a DDT process precedes, i.e., unburnt hydrogen – air mixtures are precompressed, a pressure rise ratio of 120 : 1 could result.

Explosions are rated in terms of the amount of energy released, commonly expressed as an equivalent quantity of TNT. The theoretical maximum values of explosive potentials for fuels (TNT equivalents) are recorded in Table 20. Experimental data indicate, that real yield factors of 10 % are considered reasonable. Note that hydrogen is most potent on a mass basis and least potent on a volumetric basis. It has also the least theoretical explosive potential, when equivalent energy storage is taken into account.

Preventive Measures. After analyzing accidents involving hydrogen and hydrogen-carrying equipment, preventive safety aspects are discussed in [318]. Risk avoidance by general preventive design measures, as well as reactive fire and explosion measures are presented [315], [318], [319]. In safety concepts, distinctions are made between primary, secondary and tertiary measures. *Primary safety precautions* aim at the exclusion of causative risks such as leakage, formation of explosive mixtures by proper conceptual design (inertization, open-air installation, flame arrestors, etc.). *Secondary measures* consist mainly in the avoidance of ignition sources of any kind (electrostatically or mechanically generated sparks). *Tertiary measures* should minimize dangerous results in case fire or explosion occurs. This is achieved by installation of explosion-proof or explosion relief systems, hydrogen process shut-down systems and suitable fire extinguishing systems.

Safety Regulations. Regulations (mandatory) and standards (mandatory or nonmandatory) apply for the safe production, storage and handling of hydrogen. They are mostly concerned with transportation; other operations are covered by more general regulations. Excellent listings are given for the United States [320] and for Canada [315].

United States. Examples of *nonmandatory standards* are those issued by ASME, ANSI, NFPA, etc., that may be adopted by regulatory bodies. Current *mandatory regulations* are Title 49 of CFR (Code of Federal Regulations) and the requirements of DOT (Department of Transport) and CGA (Compressor Gas Association). General industrial safety matters including the production and handling of inflammable compressed and liquefied gases are regulated by OSHA [321] (Occupational Safety and Health Administration).

Federal Republic of Germany. Mandatory regulations are Druckbehälterverordnungen (TRB, TRG, i.e., regulations for installations and examination of pressure vessels and filling thereof), Unfallverhütungsvorschrift Gase (UVV, i.e., instructions for the prevention of accidents) and GGVS and GGVE, (i.e., instructions for the transport of dangerous goods).

EEC Regulations. For the EEC the association of the European Gas Industry (IGC) is making efforts to introduce common and uniform safety standards.

Future Outlook. Considering the possible use of hydrogen in a future hydrogen energy concept (see Chap. Hydrogen Energy), no major safety problems are anticipated. Hydrogen has been handled successfully for decades in the process industries. Handling as a liquid is also routine. In comparison with other inflammable gases or liquids, the safety risk of hydrogen as a fuel is not significantly different.

7.8. Toxicology

Hydrogen does not show any physiological effect. It is nonpoisonous. Inhalation of the gas leads to sleepiness and a high-pitched voice. A danger of asphyxiation exists if the oxygen content sinks below

18 vol % because of hydrogen accumulation in the air. Direct skin contact with cold gaseous or liquid hydrogen leads to numbness and a whitish coloring of the skin and to frost bite. The risk is higher than, e.g., with liquid nitrogen because of the greater temperature differences and the higher thermal conductivity of hydrogen.

7.9. Analysis

The physical properties of hydrogen, some chemical reactions, and its nuclear spin characteristics are used for hydrogen analysis.

Hydrogen in Gas Mixtures. For rapid determination or for continuous measurement in process gases the absolute determination (or the comparison to a reference gas) of properties such as *gas density, conductivity* or *sonar velocity* can be used. The most frequently used method for analysis of hydrogen in all types of gas mixtures is *gas chromatography.* Apart from mixtures also containing helium, hydrogen is eluated first. In the case of detection with a hot-wire detector using helium as carrier gas an unusual nonlinearity exists in the conductivity of hydrogen – helium mixtures, which leads to a minimum at 8 % hydrogen. This must be taken into consideration, or alternately argon can be used as carrier gas. Hydrogen contents in the percent range can be determined by separation and integral detection according to JANAK (CO_2 as carrier gas, absorption of the carrier gas in KOH, volumetric determination of the gas in an azometer).

Gas-chromatographic determination of the six isotopic species and their nuclear spin isomers is possible. Alumina or silica gel at liquid nitrogen temperature [322] or complex polymer molecular sieves at room temperature [323] are suitable separation materials. If these are impregnated with paramagnetic substances such as Fe_2O_3 or $MnCl_2$, rapid o – p isomerization is achieved and the spin-isomer mixture corresponding to the equilibrium at the separation temperature is eluated [324].

Trace impurities in hydrogen can be determined qualitatively by low-temperature condensation or by enrichment on silica gel at low temperatures and, after desorption, they can be separated by gas chromatography. A method for the determination of traces of carbon monoxide or carbon dioxide is methanation and analyzed with hydrogen followed by methane detection with a sensitive flame ionization detector.

Chemically Bound Hydrogen. In *organic* molecules hydrogen is determined using classical elemental analysis. After the sample is weighed (usually in the micro- or submicro-range, i.e., 0.2 – 10 mg and 0.02 – 0.2 mg, respectively) it is combusted and the amount of water produced, as determined by weighing, is related to the hydrogen content. Nowadays automatic C, H, N analyzers with simultaneous detection systems are used. The content of hydrogen in *metals*, an important value for steel production, is determined firstly by vacuum extraction of the hydrogen from the heated or molten sample and, finally, by volumetric (vacuum pipette) or heat conductivity measurement [325]. In a new method, a sample is taken by inserting a porous ceramic bell and purging out the hydrogen with a nitrogen stream [326].

“Active hydrogen”, e.g., hydrogen in OH groups or in enolizable C-H-bonds, reacts with $LiAlH_4$ or metal organic methyl compounds and can be determined as hydrogen or methane volumetrically.

Modern instrumental methods are mass spectrometry and nuclear spin resonance. By means of the first method hydrogen and its isotopes in complex gas mixtures can be analyzed over a large concentration range. Nuclear magnetic resonance (^{1}H-NMR) is an invaluable instrument for the analysis and structure determination in organic and inorganic chemistry. ^{1}H-NMR spectroscopy is also applied for quantitative determination of the hydrogen content in various materials such as coal or hydrocarbons, to measure oil and water contents, e.g., in the food industry, or to pursue intricate problems in reaction kinetics [325].

[Top of Page]

8. Conventional Uses

8.1. Hydrogen in the Chemical Industry

Hydrogen is an important raw material for the chemical industry. It takes part in reactions either by addition (hydrogenation) or by means of its reduction potential. Most of the hydrogen is used for these hydrogenation and reduction processes. An overview on production and consumption structures for the Federal Republic of Germany (1978) and the United States (1984) is given in Figure 96 [328]. Changes in the production and utilization sector have been relatively little since that time. On the *production side* the fraction of the hydrogen produced using natural gas has increased at the expense of the LPG and naphtha-based plants. Some plants based on heavy oil have even been closed down and replaced by natural gas or lignite gasification plants. In the *utilization sector*, hydrogen production is stagnating. Apart from ammonia synthesis, synthesis with hydrogen – carbon monoxide gas mixtures to produce methanol, hydrocarbons and oxo-synthesis products are of particular importance. Large quantities of hydrogen are needed in refineries for hydrotreating, whereas its use in coal processing is just beginning. The use of hydrogen in metallurgy is based in particular on its reducing properties.

Figure 96. Hydrogen production and consumption structures

I Production, Federal Republic of Germany, 1978

II Consumption, Federal Republic of Germany, 1978

III Consumption, United States, 1984

At present, pure hydrogen is not used directly to produce energy (apart from space technology). Mixtures with hydrogen, however, have been used for a long time for combustion purposes. Even today the

amount of hydrogen distributed in urban or in industrial heating gas systems is very large.

In comparing the hydrogen production or usage data, a distinction must be made between the so-called captive hydrogen and the merchant hydrogen: *Captive hydrogen* uses, such as for ammonia and methanol synthesis or in various hydrotreating processes, relate to onsite hydrogen production and immediate consumption of the hydrogen. The designation *merchant hydrogen* is given to those quantities which are sold on the market. Merchant sales of hydrogen account for 10 % or less of the total hydrogen production. Import and export amounts are normally negligible. Table 38 gives a summary of a literature survey on hydrogen quantities produced as well as some forecasts for the future.

Table 38. Consumption of hydrogen and forecast consumption amounts [329-338]

	Consumption of hydrogen, $m^3 \times 10^9$		
Federal Republic of Germany	1978: 17 [329]	1984: 19.1 [330]	2000: 23 [331]
Japan		1985: 20 [335]	
United States	1978: 80 [332]	1985: 90 [333]	2000: 146 – 207 [334]
Worldwide	1980: 300 [336]	1986: 500 [337]	2025: 1500 – 2000 [338]

8.1.1. *Ammonia Synthesis*

Hydrogen reacts with nitrogen to yield ammonia. The reaction is exothermic.

$$3\,H_2 + N_2 \rightleftharpoons 2\,NH_3;\quad \Delta H_{298} = -91.22\,kJ/mol$$

For details on the properties, production and usage of ammonia see ⟶ Ammonia.

Technical ammonia syntheses are operated at 15 – 25 MPa. On a catalyst the reaction starts at ca. 350 °C, maximum reaction rates are reached in the range of 470 – 530 °C.

1 965 m^3 (STP) of hydrogen and 668 m^3 (STP) of nitrogen are necessary for each tonne of ammonia produced. For hydrogen production, the usual processes are suitable (see Section Production from Coal and Hydrocarbons). The production of the ammonia synthesis gas is usually followed directly by the ammonia synthesis. The necessary nitrogen content in the synthesis gas is introduced by the addition of air in a secondary reformer or via a liquid nitrogen scrubber. The conversion achieved per pass is ca. 25 – 35 %, so that a recycle loop is installed. Condensed liquid ammonia is removed continuously. Impurities containing oxygen, such as carbon monoxide, carbon dioxide, oxygen and water, are catalyst poisons and must be completely removed from the synthesis gas.

The make-up gas to the synthesis loop contains certain amounts of inert gases such as methane (from methanation), argon (from the process air) or helium (from natural gas). To prevent accumulation of the inert gases in the synthesis reactor, some recycle gas must be continuously removed from the loop, thus causing a loss of hydrogen. Most plants nowadays have a recovery unit:

- cryogenic hydrogen recovery units, sometimes combined with argon production (see Section Low-Temperature Processes)
- PSA hydrogen recovery units (see Section Adsorption Processes)
- membrane separation hydrogen recovery units (see Section Permeation Processes).

Hydrogen recovery by reversible hydride formation has also been suggested [339].

Modern synthesis plants have a capacity of 1000 – 2000 t/d; this corresponds to an hourly hydrogen requirement of 80 000 – 160 000 m^3 (STP). At present 75 – 80 % of the synthesis hydrogen is produced from natural gas, naphtha or LPG. 10 – 15 % are made from heavy fuel oil by partial oxidation and ca. 5 % from coal. Electrolysis hydrogen is used for ammonia production only in special cases, e.g., if cheap electric power is available. Small units are situated in Norway, Peru and Egypt [340], producing ca. 5 % of the world production of hydrogen.

An ammonia molecule contains three hydrogen atoms. For hydrogen utilization in future energy systems (see Chap. Hydrogen Energy), ammonia has often been suggested as a carrier. Hydrogen could be stored and transported more economically in the form of ammonia [341], but the latter is untenable as a direct fuel because of its toxicity and the formation of NO_x. However, on reconverting the ammonia to hydrogen the stored energy can be made available at any desired site. An overview of the possibilities of an ammonia-hydrogen concept in energy technology is given in [342].

8.1.2. *Hydrogen in Refinery Processes (⟶ Oil Refining)*

In refineries hydrogenation processes are included to increase the hydrogen content of the heavy crude oil fractions and to produce lighter fractions by reduction of the molecular mass. At the same time, undesirable elements, such as sulfur, nitrogen and metals, can be removed. For this group of related processes the designation hydroprocessing is used.

Process Fundamentals. Hydrogenation processes are characterized according to the feedstock, the partial pressure of the hydrogen used and the reaction temperature (see Fig. 97) [343]. In

hydrotreating processes addition reactions and hydrogenating cleavage (hydrogenolysis) occur. In *hydrocracking processes* mainly dehydrogenation, cracking, isomerization and dealkylation reactions take place. For the catalysts used in the individual processes, promoter and carrier materials, selectivity, life-times, coke and metal deposition see [344]; a compilation of available hydroprocessing catalysts is given in [345]. Newly developed bi- or multifunctional catalyst systems based on zeolites combine cracking functions on acid centers of the carrier materials with hydrogenation and dehydrogenation functions of the active metal components.

Figure 97. Process temperatures and pressures of refinery hydrogenating processes

a) Hydrocracking; b) Residue desulfurization; c) Heavy gas oil catalytic cracker feed hydrofining; d) Middle distillate; e) Naphtha hydrofining

The processes are carried out in one or two stages in the gaseous or liquid phase. Table 39 shows some examples of the most important hydroprocessing routes, typical process conditions and product ranges. Overviews are given in [346] and [347].

Table 39. Feed and product characteristics and process parameters of various hydrogenation processes during hydroprocessing

[a] VGO = vacuum gas oil.
[b] RON = research octane number.

The use of hydrogen has also been suggested in other refinery areas; addition of hydrogen to the crude oil distillation is reported to make this more economic (*hydrostripping*, [348]). Subjecting residual oils or heavy crudes to hydrogen for short periods at high temperatures and pressures of up to 50 MPa leads to feed upgrading (*hydropyrolysis*, [349]).

Hydrogen Requirements. The hydrogen necessary for the hydroprocessing is produced in the refinery. The main source is the catalytic reforming unit where ca. 45 m^3 of hydrogen per ton of processed crude oil is produced. Additional hydrogen is produced by steam reforming of methane, LPG, and naphtha, and by partial oxidation. In the United States 60 – 70 % is produced by catalytic reforming, 30 % by steam reforming, and 2 % by partial oxidation.

The connections between processes utilizing and processes producing hydrogen in oil refining operations are shown schematically in Figure 98.

Figure 98. Integration of H_2-producing and H_2-consuming process units into crude oil processing

⇒ H_2 units from H_2-producing process

⇒ H_2 units to H_2-consuming process

The carbon:hydrogen ratio in the feedstocks (heavy and residual crudes, tar sands, oil shale) as well as their sulfur, nitrogen and metal components will become increasingly unfavorable in the future. To cover the expected increasing hydrogen demand it is necessary to improve the hydrogen recovery in refineries and, eventually, to utilize other potential sources of byproduct hydrogen.

8.1.3. *Hydrogen in Coal Refinement*

Coal refinement processes which are performed in the presence of hydrogen are coal hydrogenation, hydropyrolysis and hydrogenating coal gasification.

Coal Hydrogenation. (⟶ Coal Liquefaction – Direct Coal Liquefaction, the first three Sections). By thermal or thermocatalytical treatment in the presence of hydrogen under pressure, coal is almost completely converted into liquid and gaseous products (direct coal liquefaction). Details of the chemical fundamentals, types of process and reaction techniques are given in [350]; the use of catalysts is described in [351]. The reaction is catalyzed by iron compounds (sulfides or oxides), molybdenum, cobalt and tin or even mineral clays. Catalysts which can be cheaply disposed of are especially favored, but also highly-active cobalt – molybdenum carrier catalysts are being investigated.

Hydrogen can either react directly (in its molecular form) with coal (direct hydrogenation) or it can be transferred by means of hydrogen-carrying solvents (donor solvent coal liquefaction or hydrogenating extration) (⟶ Coal Liquefaction – Exxon Donor Solvent Process). This type of process with chemically bound hydrogen can be carried out in the presence of an additional amount of molecular hydrogen and is known as short hydrogenation, the product being primarily bitumen or solvent-refined coal (SRC).

Hydrogen is required for the important process stages, such as hydrogenative cracking in the slurry phase (feedstock slurries of hard coal, lignite or coal extract), cracking and refining hydrogenation in mixed phases (feedstock hydrogenation residues, tars) and for cracking and refining hydrogenation in the gas phase (feedstock middle distillates and bottom cuts). Donor solvent processes employ external, catalytical or noncatalytical hydrogenation of the recycled solvent.

Hydrogen Consumption and Product Range. The products obtained range from small quantities of coal residue over heavy and middle distillates and gasoline to gases. The boiling range of the hydrocarbon products depends on the quantity of hydrogen. This is shown in Figure 99 for hydrogenation in the slurry phase. Hydrogen consumption per tonne of dry coal for the catalytic direct coal hydrogenation amounts to ca. 1000 m^3.

Figure 99. Relation of hydrogen consumption and product distribution during slurry-phase hydrogenation of coal

Hydrogen Production, Recycle Gas Separation. In all coal hydrogenation processes nonreacted hydrogen must be recovered and recycled back to the reaction together with fresh make-up hydrogen. The economics of the projected large-scale processes for direct hydrogenation depend not only on the further improvement of the hydrogenation stage (milder hydrogenating conditions, improved liquid product yields) but in particular on:

improved separation of the gaseous hydrogenation products with complete recycle of hydrogen with an acceptable purity (inert components decrease the partial pressure of the hydrogen) and low-cost production of the make-up hydrogen using improved and integrated processes for steam reforming and partial oxidation of byproducts of the coal hydrogenation, which are otherwise

difficult to utilize.

Process Developments. After the oil embargo of 1973, many developments were revived. The developments being furthered in the Federal Republic of Germany are based to a great extent on the *modified IG process.* Two plants on a pilot scale (6 t/d and 200 t/d) have been erected. In the United States, on the other hand, the process concepts being pursued involve new process steps, e.g., SRC 1, SRC 2 (Gulf Oil), Exxon Donor Solvent Process, H-coal process (Hydrocarbon Research). An overview is given in [352]. Improved two-stage processes are finding increasing attention, for example in Japan [353].

Hydropyrolysis. In this process coal is subjected to high temperatures (700 – 1000 °C) for short residence times in the presence of hydrogen and thereby thermally cleaved and partially hydrogenated (flash pyrolysis). The hydrogen consumption of 200 – 300 m^3 per tonne of coal is relatively low and 25 – 45 % liquid hydrocarbons are obtained; about half of the feedstock coal is recovered in the form of a low-sulfur residue coke [354].

Hydrogasification of Coal. In hydrogasification processes, coal is converted in the presence of hydrogen and/or steam in one stage or in a series of stages directly to methane. The aim of many process developments is the production of SNG.

The basis is the strongly exothermic reaction of hydrogen with carbon according to (greatly simplified):

$$C_{(coal)} + 2\,H_2 \rightarrow CH_4;\;\; \Delta H_0 = -87.4\,kJ/mol$$

Equilibrium data are given in [350]. The equilibrium yield of methane is increased at high pressure and low temperature. Table 40 shows calculated methane concentrations at equilibrium. The reaction sequence is a combination of the rapid hydrogenating gasification of the organic components in the coal and the slow heterogeneous gas – solid reaction between semicoke or coke residue and molecular hydrogen. The reaction occurs relatively slowly in the temperature range of 700 – 1300 °C; the technically feasible operating conditions are nowadays considered to be between 800 and 900 °C and 4.0 – 10.0 MPa. The multiphase reaction must be conducted in a fluidized bed and, because of the short residence times resulting, gas recycle processes must be used.

Table 40. Methane concentrations of the carbon hydrogenation reaction at equilibrium

Temperature, °C	Pressure, MPa	CH_4 content, vol %
800	1	26
	10	63
	100	87
1000	1	8
	10	37
	100	72

Most important for the economics are the hydrogen production costs. The overall methane yield per kilogram of carbon depends in particular on the process used to produce hydrogen:

hydrogen from the coal feedstock, autothermal	0.6 m^3 (STP) CH_4 per kilogram of carbon
hydrogen from recycle methane, allothermal	1 m^3 (STP) CH_4 per kilogram of carbon
hydrogen from external sources, e.g., water electrolysis	1.8 m^3 (STP) CH_4 per kilogram of carbon

Examples. The process developed by *Union Rheinische Braunkohlenkraftstoff AG* operates in a fluidized bed at 800 – 1000 °C and 5.5 – 9.5 MPa (data from the pilot plant operation). The crude gas obtained contains up to 40 % methane; the degree of gasification is ca. 82 %. For hydrogen production the residue coke is gasified in a High-Temperature Winkler (HTW) gasifier [355].

Hygas process (Institute of Gas Technology, United States): Hydrogen is produced from the residue coke in the lower part of a multistage reactor.

The *Hydrane process* (Bureau of Mines, United States) uses a two-stage gasifier with external hydrogen production from residue cokes, oxygen and steam.

8.1.4. *Synthesis Gas*

The process for the production of hydrogen from hydrocarbons yields gas mixtures containing mainly hydrogen and carbon monoxide (see Section Production from Coal and Hydrocarbons). Such gases are named synthesis gases since they are used for the synthesis of special chemical products. Some hydrogen – carbon monoxide combinations (because of the production method or the final use) have the designation water gas, cracked gas, methanol synthesis gas or oxo-synthesis gas. The fundamental reactions of synthesis gas chemistry are methanol synthesis, Fischer – Tropsch synthesis, oxo synthesis (hydroformylation), and methane synthesis; further synthesis gas reactions are being developed. Excellent overviews are given in [356][357][358].

Methanol Synthesis. Methanol can be produced from hydrogen – carbon oxide mixtures by means of the catalytic reaction of carbon monoxide and some carbon dioxide with hydrogen. Methanol may be considered virtually as synthesis gas at maximum compression.

$$CO + 2\,H_2 \rightleftharpoons CH_3OH \quad \Delta H^0 = -90.84\,kJ/mol$$

$$CO_2 + 3\,H_2 \rightleftharpoons CH_3OH + H_2O \quad \Delta H^0 = -49.6\,kJ/mol$$

The presence of a certain amount of carbon dioxide in the percentage range is necessary to optimize the reaction. Side reactions, also strongly exothermic, can lead to formation of byproducts such as methane, higher alcohols, or dimethylether.

2520 m^3 (STP) of synthesis gas (70 % H_2, 21 % CO, 7 % CO_2) are necessary to produce a tonne of methanol. The purity of the latter depends on the catalyst used. Copper – zinc catalysts used in the low-pressure process require a sulfur-free gas (H_2S <1 ppm [mL/m^3]). Catalysts for the high- and medium-pressure processes (ZnO activated with chromic acid) can accept 30 ppm (mL/m^3) of hydrogen sulfide. For details on the process schemes, catalysts, process techniques, economics, etc. see, for example, [360].

Fischer – Tropsch Synthesis. Hydrogen – carbon monoxide mixtures react to hydrocarbons according to reaction equations (58) – (62), (60) is the main secondary reaction. An example for one of the general equations for alkane synthesis is (63), for olefin synthesis (64). The overall reaction balance including synthesis gas formation corresponds to an indirect coal hydrogenation.

$$CO + 2\,H_2 \rightarrow -CH_2- + H_2O \quad \Delta H^0 = -165.0\,kJ/mol \tag{58}$$

$$2\,CO + H_2 \rightarrow -CH_2- + CO_2 \quad \Delta H^0 = -204.7\,kJ/mol \tag{59}$$

$$CO + H_2O \rightarrow H_2 + CO_2 \quad \Delta H^0 = -39.8\,kJ/mol \tag{60}$$

$$3\,CO + H_2O \rightarrow -CH_2- + 2\,CO_2 \quad \Delta H^0 = -244.5\,kJ/mol \tag{61}$$

$$CO_2 + 3\,H_2 \rightarrow -CH_2- + 2\,H_2O \quad \Delta H^0 = -125.2\,kJ/mol \tag{62}$$

$$nCO + (2n+1)H_2 \rightarrow C_nH_{2n+2} + nH_2O \tag{63}$$

$$nCO + 2\,nH_2 \rightarrow C_nH_{2n} + nH_2O \tag{64}$$

The Fischer – Tropsch synthesis is strongly exothermic. The total heat of reaction amounts to ca. 25 % of the heat of combustion of the synthesis gas. Undesirable side reactions include methanation, the Boudouard reaction, coke deposition, oxidation of the catalyst, or carbide formation. Other competing reactions such as alcohol, aldehyde, ketone, carbonic acid, and ester formation, also occur.

For development of the process, kinetics, thermodynamics and mechanism of the reactions, distribution of the products, etc., see ⟶ Coal Liquefaction and [359-362]. Up to 1954 4 000 publications and 4 020 patents regarding Fischer – Tropsch catalysts had already been reported [363], but virtually only those based on cobalt and iron have been successful.

The yield of the Fischer – Tropsch synthesis is determined by the initial hydrogen – carbon monoxide ratio and the stoichiometric requirements of the desired reaction products. The maximum yield is obtained when the aforementioned are nearly equal and thus yield 208.5 g hydrocarbon from 1 m^3 (STP) of synthesis gas; technically ratios of 1.7 : 1 to 3 : 1 are used.

The Fischer – Tropsch synthesis is used on a technical scale nowadays only in South Africa at SASOL. At SASOL I, five units of the ARGE reactor of the Ruhrchemie – Lurgi (gas phase, fixed bed reactors, 2.3 – 2.5 MPa, 220 – 250 °C, 40 m^3 Fe – Cu – K_2O – SiO_2 catalyst, 9 – 12 months running time) and three reactors using the Synthol circulating fluidized bed of Kellogg – SASOL (gas phase, 2.0 – 2.3 MPa, 300 –340 °C, 30 – 140 t Fe catalyst produced by reduction of magnetite; running time 45 d) are in operation. At SASOL II (start-up 1980) and SASOL III (start-up 1982) only the more flexible Synthol process is used. The enormous gas amounts (2×1 650 000 m^3 [STP]/h raw gas, 2×1 000 000 m^3 [STP]/h feed gas) make the recovery of byproducts (ethylene, alcohols esters, carbonic acids, etc.) economically worthwhile [364].

Variations of the Fischer – Tropsch synthesis with other selective catalysts can lead to the following products:

low-molecular-mass olefins (C_2 – C_4, mostly ethylene) [365], [366]
medium- and long-chain olefins [366]
polyethylene [367]

Polyethylene is obtained at high pressures (100 – 200 MPa), low temperature (100 – 120 °C), and using a ruthenium-based catalyst.

Methane Synthesis. The catalytic hydrogenation of carbon monoxide to methane is strongly exothermic

$$CO + 3\,H_2 \rightarrow CH_4 + H_2O \quad \Delta H = -206.4\ \mathrm{kJ/mol}$$

Consecutive and side reactions (shift conversion, Boudouard equilibrium, hydrogenation of carbon) make the calculation of equilibrium conditions very complex. The influence of the feed gas composition and operating parameters on the equilibrium composition of the product gas and the kinetic data, which are somewhat contradictory, are summarized in [368].

Classical methanation catalysts are magnesium-promoted nickel catalysts with diatomaceous earth as carrier. Catalyst developments are aimed at increasing the thermal and mechanical stability and yielding catalysts which are simultaneously suitable for the cracking of naphtha with subsequent methanation. Methanation is technically important as a catalytic purification step for the removal of carbon monoxide from gases (see Section Catalytic Gas Purification).

Hydroformylation of Olefins. Hydroformylation, also called oxo synthesis or Roelen reaction (O. Roelen, 1938), is a commercial-scale process for the production of aldehydes. By catalytic addition of hydrogen and carbon monoxide to an olefin an aldehyde is obtained under chain elongation

Hydroformylation is generally an exothermic, homogeneously catalyzed liquid-phase reaction of the olefin with hydrogen and carbon monoxide. As catalyst cobalt carbonyl hydride or, in some variations of the oxo-synthesis, cobalt- or rhodium-phosphin complexes are used.

Propen is the olefin mostly used. The oxoproducts are converted to alcohols, carboxylic acids, aldol-condensation products, and primary amines. About 20 commercial processes are state of the art. An excellent review is given in [369] (see ⟶ Oxo Synthesis).

Homologation. Under the reaction conditions of the hydroformylation alcohols and aldehydes react with carbon monoxide – hydrogen under elongation of the chain by one CH_2- unit

$$R-CH_2-OH + CO/H_2 \rightarrow R-CH_2-CH_2-OH + H_2O$$

Homologation has been performed with a number of alcohols, the production of ethanol from methanol has been most intensively investigated. The homologation is not used industrially because of the many side reactions which take place [370].

Synthesis Gas as Chemical Feedstock. Hydrogen – carbon monoxide mixtures, hydrogen alone, and their primary product methanol are important feedstocks for the chemical industry. Nowadays, ethylene which is produced from propane, ethane, naphtha, or gas oil is the most important feedstock for the production of industrial organic chemicals in the chemical industry. Bascially, it is, however, possible to obtain these compounds from synthesis gas thus changing the feedstock basis to coal (see Fig. 100).

Figure 100. Synthesis gas as feedstock in the chemical industry

8.1.5. ***Hydrogen in Organic Synthesis***

Hydrogen is required for the production of chemicals and intermediates in organic chemistry. A large number of hydrogenations or reductions are carried out on a technical scale (⟶ Hydrogenation and

Dehydrogenation).

Activated and nonactivated double and triple bonds in olefins and acetylenes can be easily partially or totally hydrogenated, whereas the hydrogenation of aromatic and heterocyclic bonds requires more energetic conditions. Functional groups, such as carbonyl, nitro, nitroso, and nitrile groups, can also be hydrogenated.

The reaction conditions are dictated by equilibrium (65). The reactions are exothermal and run in the presence of a catalyst.

$$A + nH_2 \rightarrow BH_{2n} \tag{65}$$

Directions for carrying out catalytic hydrogenations on a laboratory or industrial scale are given in [371]. Summaries of hydrogenation reactions are given in [372] and [373]. Hydrogenation catalysts are metals of groups 8 – 10 of the periodic system (see front matter of this volume), e.g., Raney nickel, as well as copper and molybdenum. In particular the noble metals (Pt, Pd), are highly-active catalysts [374]. Homogeneous systems with molecularly dispersed catalysts in the solution, can be used for special synthesis problems (selective hydrogenation, asymmetric synthesis) but are at present of no great importance in commercial areas because of the frequently encountered difficulty to remove the catalyst from the reaction mixture. Table 41 gives an overview of commercially used hydrogenation reactions.

Table 41. Selection of important industrial hydrogenation reactions

Reaction	Product	Process features	Uses
Hydrogenation of unsaturated hydrocarbons and aromatics			
 (analogous: cyclohexanol from phenol, cyclohexane carboxylic acid from benzoic acid)	cyclohexane	middle pressure hydrogenation over Ni-/Pt-Li-Al_2O_3 catalyst in liquid phase (IFP, Mitsubishi) gas phase (UOP, DSM, Thoray, Houdry)	starting material for nylon production (cyclohexanone/ol, adipic acid, caprolactam), solvent
$CN-CH_2-CH=CH-CH_2-CN + H_2 \longrightarrow CN-(CH_2)_4-CN$	adiponitrile	Du Pont (300 °C), liquid phase hydrogenation 25–30 MPa/70–100 °C over Raney nickel	hexanediamine
$OH-CH_2-C\equiv C-CH_2OH + 2H_2 \longrightarrow OH-(CH_2)_4-OH$	butanediol	trickle bed, 20 MPa, 180–200 °C Ni catalyst with Cu-, Cr-promotors	polyesters, polyurethane-plasticizer component, solvent
 Selective hydrogenation as purification step during production of ethylene, propene, and butadiene	sulfolane	Shell process, 11 000 t/a	aromatics extraction solvents, sour gas, scrubbing agent
Further processing of oxo-products			
$R-C(=O)H + H_2 \longrightarrow R-CH_2OH$ (analogous: ethylhexanol from ethylhexanal)	oxo-alcohols	gas phase hydrogenation at 2–0.3 MPa/115 °C, Ni catalyst sump phase hydrogenation, 8 MPa/115 °C Ni catalyst	components for solvents, plasticizers, detergents
$R-C(=O)H + NH_3 + H_2 \longrightarrow R-CH_2-NH_2$	primary amines	hydrogenation (up to 30 MPa, 25–130 °C), Raney nickel catalyst	
Hydrogenation of other ketones and aldehydes			
Maleic acid $\longrightarrow$ butyrolactone $\longrightarrow OH-(CH_2)_4-OH$	butanediol	Mitsubishi, Kao Ind. (Japan) process	
	bis-(hydroxymethyl)-cyclohexane	two step Eastman-Kodak process	

Reaction	Product	Process features	Uses
$CH_2{=}CH{-}C(=O)H + H_2 \longrightarrow CH_2{=}CH{-}CH_2OH$	allylalcohol	Degussa gas phase process (heterogenous catalysis)	starting material for glycerol, glycidol
2 Acetone $\longrightarrow$ mesityl oxide $\xrightarrow{\text{Pd zeolite}}$ $i\text{-Bu}{-}C(=O){-}CH_3$	MIBK	hydrogenation at Pt–zeolites (modified one step processes)	(extraction) solvent
Fats, oils + $H_2 \longrightarrow R{-}CH_2{-}OH$	fatty alcohols	20–40 MPa/200–400 °C, catalysts of Adkins-type	
$R{-}O{-}CH_2CH_2{-}OH + HCHO + H_2 \longrightarrow R{-}O{-}CH_2CH_2{-}OCH_3$	polyethylene-glycol ethers	new Hoechst process	sour gas scrubbing agent (Selexol)
Hydrogenation of N-compounds			
	aniline	fixed bed hydrogenation over NiS/CuS, 300–475 °C (Bayer, Allied, Lonza), fluidized bed hydrogenation, 5 MPa/100 °C over Cu catalyst (BASF, Cyanamid)	starting material for dyes, pharmaceuticals, isocyanate polymers, solvents
	diaminotoluenes	analogous to nitrobenzene reduction	
Nitriles + $H_2 \rightarrow$ primary amines	hexanediamine	5–15 MPa/60–130 °C over Raney Ni or Raney Co	starting material for fibers, sour gas scrubbing agent
Miscellaneous reactions			
	benzene	3–5 MPa/500–650 °C over Cr_2O_3–Mo_2O_3–CoO catalyst (Houdry, UOP, Shell, BASF) 10–25 MPa/400–500 °C over Pt–Al_2O_3–SiO_2	50 % of toluene production further processed to benzene
Xylene isomerization under H_2 partial pressure	o-/p-xylene	catalysts	terephthalic acid, phthalic acid

High-purity hydrogen is necessary for the partial or total hydrogenation of fats and oils (for the production of edible fats or for technical purposes). In fat hydrogenation the polyene, triene, and diene fatty acids in their glyceride form are selectively hydrogenated to the corresponding monoene acids.

The industrial production of sugar alcohols, such as sorbitol, xylitol or mannitol from the corresponding sugars is carried out by catalytic hydrogenation. Batch suspension processes using Raney nickel catalysts are mainly employed under reaction conditions of 120 – 150 °C and 3 – 7 MPa [375].

8.1.6. *Hydrogen in Inorganic Synthesis*

The catalytic hydrogenation of anthraquinone and its derivatives followed by their auto-oxidation to yield hydrogen peroxide is the basis of the commercially important process for hydrogen peroxide production (⟶ Hydrogen Peroxide – Anthraquinone Process (AO Process)). Further important reactions in inorganic chemistry are the production of hydrochloric acid from hydrogen and chlorine (⟶) and the hydroxylamine synthesis (⟶ Hydroxylamine).

8.2. Hydrogen in Metallurgy

Iron Metallurgy. To reduce iron ore, apart from coke (classical blast furnace process), other reducing agents can be used. For reduction a gas containing hydrogen, carbon monoxide, or mixtures of these is suitable. The reduction gas is produced by steam reforming or partial oxidation of fossil fuels. These *"direct reduction"* processes (⟶ Iron – Production) yield sponge iron, which can be melted to give crude iron which is further processed to steel.

The leading direct reduction technologies are the Midrex, the HyL I, and the HyL III process with 90 % of the total capacity [376]. The hydrogen content of the reducing gas is ca. 40 – 65 vol % (Midrex, shaft furnace) and 75 vol % (HyL III, retorts). To fully utilize the reduction potential of the gas, carbon dioxide and water vapor are removed and the gas is recycled.

The use of *pure hydrogen* has advantages with respect to the reaction time, the degree of reduction and the texture of the reduced pellets [377], but the carbidizing reaction necessary for steel production cannot take place, so that reduction with pure hydrogen has not been able to establish itself.

Nonferrous Metallurgy. Hydrogen is employed as reducing agent and as utility in some powder metallurgy production processes. Table 42 shows the use of hydrogen during the production and handling

of various nonferrous metals.

Table 42. Use of hydrogen in the nonferrous metallurgy

Metal	Unit operation	Product
Copper	reduction of copper salt solutions under pressure	Cu powder
Nickel	selective reduction during cobalt production	Ni powder
Cobalt	reduction of aqueous cobalt salt solutions under pressure (4 MPa, 175 °C)	Co powder
Molybdenum, tungsten	reduction of the oxides or molybdates and tungstenates	Mo, W powder
Tantalum	reduction of tantalum chloride, $TaCl_5$, in hydrogen plasma	Ta hydride, Ta powder
Germanium	reduction of germanium tetroxide, GeO_4, at 650 °C	Ge powder for further processing in zone melting
Uranium	reduction of the higher uranium oxides at 650 °C	UO_2

For recovery of copper from its sulfidic ores reduction with hydrogen in the presence of calcium oxide has been suggested [378]. The thermodynamically unfavorable position of the hydrogen reduction reaction on metal sulfides is improved by the removal of the developing hydrogen sulfide (as CaS) from the equilibrium mixture.

8.3. Other Uses

Use of the High Temperature of the Oxyhydrogen Flame. The combustion of a stoichiometrical hydrogen – oxygen mixture leads to flame temperatures in the range of 3000 – 3500 K. Such flames can be used for:

Cutting and autogenous welding in the metal industry.
Growing synthetic crystals (saphires, rubies) by melting aluminum oxide doped with the appropiate metal oxides.
Production and handling of quartz glass (melting of rock crystals).

A process for the production of olefins from hydrocarbons is described [379]. The hydrocarbon to be cracked is atomized and fed into a 1000 – 2000 °C hot gas stream of hydrogen and steam, which is produced in a prereactor by combustion of excess hydrogen in oxygen. High olefin yields are reported to be possible even from heavy hydrocarbons.

Hydrogen Plasma as a Heating Agent. A further temperature increase by using the free energy of the hydrogen combustion reaction is hindered by strongly endothermic processes, such as the onset of molecule dissociation and ionization of the atoms. Higher temperatures can be reached in a plasma gas produced by means of an electric arc or a high-frequency field. Hydrogen dissociates around 5000 K into hydrogen-atoms, which start to ionize to H^+ at 9000 K; the recombination of ions to atoms or of atoms to molecules produces a great amount of heat. The heat content of hydrogen plasma is used in some processes for the production of acetylene from hydrocarbons (see Section Production from Coal and Hydrocarbons; ⟶ Acetylene – Production from Coal (Arc Coal Process)). Hydrogen plasma has advantages compared to ordinary electric arc pyrolysis, for example, much lower carbon formation.

Hydrogen in Metal Processing. The high temperature of the plasma stream is used for plasma welding and cutting. The addition of hydrogen to plasma argon (2 – 15 vol %) increases the temperature and the cutting velocity. This process is used principally for cutting or welding high-alloy steels. Forming gas, a gas mixture of 8 – 20 % hydrogen and nitrogen, prevents the oxidation at the far side of the weld (root cut), e.g., when pipes are being welded.

In the thermal atomization technique for the production of surface layers, a plasma jet is used to spray high-temperature melting metals, their oxides, borides, etc. As plasma gas hydrogen, hydrogen – nitrogen or hydrogen – argon mixtures can be used.

Heat treatment of metals (annealing, sintering, melting) requires the presence of an inert atmosphere. A mixture of nitrogen with hydrogen is usually used. Hydrogen alone can decrease the annealing time by 30 % because of its higher heat conductivity and the shorter reaction times for the reduction of oxide layers [380]. Mixtures of nitrogen, hydrocarbons, and hydrogen are used for nitriding and carbonizing annealing.

During the production of plate glass by the float glass process, a protective nitrogen – hydrogen atmosphere is employed to keep the metal melt surface free of oxides.

Semiconductor Technology. For the production of doped semiconductors, traces of the elements in the form of the corresponding hydrides (SiH_4, AsH_3, GeH_4) are mixed with a high-purity hydrogen stream in the required concentration and deposited by thermal decomposition on a silicon carrier.

Water Treatment. In potable water, unduly high nitrate contents can be lowered by denitrification with hydrogen-oxidizing bacteria in bioreactors. Hydrogen, dissolved at 0.4 – 0.6 MPa, is used as an

energy supply for the biomass [381]. For the treatment of boiler feed and process water, dissolved oxygen can be removed by conversion with hydrogen in the presence of palladium-doped exchange resins.

Other Uses. Hydrogen is also used for the following purposes: as alloying element in metals to produce required chemical properties, and to increase the transition temperature of superconducting alloys, as well as carrier and fuel gas in gas chromatography (flame ionization detector). Liquid hydrogen is used as a refrigerant, e.g., in bubble chambers [382] and for cooling of superconducting metals below the transition temperatures.

[Top of Page]

9. Hydrogen Energy

Rev. WILLIAM CECIL of Cambridge, England, is the first person reported to have suggested using hydrogen in an engine in 1820. In 1874, JULES VERNE described in one of his last books “the fuel to be used, once coal, ran out . . . – Water . . . but decomposed into its primitive elements . . . and decomposed, doubtless, by electricity.” Unfortunately, he did not disclose any details on the nature of the primary energy source to split the water.

In the 1920s and the 1930s, a great number of scientists, especially J.B.S. HALDANE in Scotland and R. ERREN in Germany, described virtually every method of production, storage and application mentioned so far in today's hydrogen energy concept, e.g., electricity generation using wind turbines, electrolysis, hydrogen storage in liquid form, and utilization in fuel cells and aircrafts. More on the story of hydrogen energy in general can be found in [383].

9.1. Aims of the Hydrogen Energy Economy

Hydrogen is an energy carrier, an indirect source of energy, not a resource itself. In spite of this, hydrogen was at first foreseen as a substitute energy form, in particular to substitute coal, natural gas, oil, and any products derived from them.

The reserves of fossil energy, in particular oil, are limited. This led to the belief that hydrogen could soon be used economically as a substitute energy form. The economic viability of the energy carrier hydrogen is enhanced by price advantage in transport over large distances (see Section Hydrogen Energy Economics) and the possibility of energy storage (see Section Hydrogen-Energy Conversion Systems).

According to Figure 14, hydrogen for use as a universal energy carrier can be generated by using all possible primary energy sources. Coal, nuclear energy including fusion (although still undeveloped), and solar energy have been named.

In addition to economic reasons for the introduction of new energy sources and new energy carriers, ecological reasons are becoming increasingly important, for example:

The increasing carbon dioxide content of the atmosphere, caused by the use of fossil energy sources (Fig. 101) and other human activities such as destruction of the tropical rain forests are predicted to lead to extensive climatic changes, e.g., a slow warming up of the atmosphere and the oceans, and melting of pole caps [384], [386]. Because of the natural fluctuations in the climate this theory has not been proven beyond doubt. In particular, little is known about compensation effects.

Figure 101. Actual and projected increase of the CO_2 content of the atmosphere, caused by human action, especially burning of hydrocarbons, coal, and wood

A) Measurements in Hawaii [385] from 1959 to 1983; B) Some projections extrapolating two scenarios of energy use

a) Maximum use; b) Optimum conservation of natural resources [384]

Well-known scientists have been demanding for years (without success) that a “low-risk strategy” for the use of fossil resources should be followed [387]. The utilization of the energy carriers coal, oil (in the form of gasoline, diesel, kerosene, etc.) and natural gas leads to emissions of sulfur dioxide, nitrogen oxides and hydrocarbons. In Europe, this has already led to the destruction of extensive wooded areas and to damage of the rest of the forests. The use of hydrogen as an energy carrier coupled with suitable utilization techniques could become particularly important for environmental protection.

Hydrogen competes with the conventional energy carriers hydrocarbons (methane, LPG, gasoline, etc.), coal, and electric power.

Further energy carriers are those recovered from regenerable sources and from refuse: biogas, alcohols, and vegetable oils.

For the suitability of an energy carrier, the following aspects are important:

- conversion efficiency of the primary energy carrier to the final use,

availability,
ease of storage,
safety, and
ecological and economic evaluation

The evaluation of the energy carriers for specific applications is given in Section Hydrogen-Energy Conversion Systems, the safety aspect is treated in Section Safety Aspects.

9.2. Production Systems for Hydrogen Energy

For use as a chemical reactant hydrogen is produced almost exclusively from hydrocarbons (see Table 11), because integration into the production processes and resulting overall plant economics are determining. A future hydrogen energy concept should be based on forms of energy which influence the environment as little as possible. It should offer overall economic advantages and should be socially acceptable. This is the case with solar energy, used (1) directly in photovoltaic or solarthermic plants or in direct hydrogen production, (2) climatically induced energy gradients, e.g., wind, waves, heat, (3) indirectly via production of biomass (carbohydrates, plant oil, ethanol, etc.). As an intermediate solution for a limited transition period a combined utilization of fossil primary energy, nuclear energy and regenerable energy forms have been suggested.

Figure 14 gives a review of the principal possibilities of generating hydrogen from the primary energy sources solar energy, fossil fuels, nuclear and geothermal energy. In hydrogen energy scenarios, the economical and ecological aspects of the conversion of primary energy to the required energy form heat, power, light, etc., using hydrogen as energy carrier is investigated from the point of view of present technologies.

9.2.1. *Energy Sources*

Direct Solar Energy. Solar radiation can be directly used to produce hydrogen (see Section Other Methods for the Cleavage of Water) by means of photochemical, photobiological or photoelectrochemical effects.

These methods, however, have up to now been only able to produce small amounts on a laboratory scale. The catalysts and the biomass tested have a short lifespan. Developments, especially in the area of basic research, are being followed up.

Thus, the short-term realization of projected hydrogen production systems is based on the indirect utilization of solar energy using photovoltaic cells (⟶ Photovoltaic Cells) with which electricity or, more exactly, electric voltage is produced. In addition, solar-thermal power stations, in which utilizable energy in the form of heat is developed, will become operable. In particular, the photovoltaic technology is already intensively utilized. Not only plants for power production, but also pilot hydrogen producing systems are already in operation or under construction.

Utilization of solar energy for photovoltaic power production is possible all over the world. The energy utilization factor in countries with high sunshine intensity (e.g., Sahara) is ca. 2.5 times higher than in the temperate climate zones (mid Europe) [388].

Those areas which are considered to be very good sites have a radiation energy > 2300 kWh/m^2 per year. If not only the high sunshine intensity, but also the geological suitability for setting up solar cell modules is considered, then ca. 6×10^5 km^2 are available worldwide; this is less than 0.5 % of the surface area of the globe. This area alone would be sufficient at a hydrogen production equivalent to 7000 tce/km^2 (tce = tons of coal equivalent, 1 tce $\hat{=}$ 29.31×10^9 J) per year, to cover the world energy consumption [389]. But also other concepts which do not concentrate as much on the areas with high radiation intensity, but on installation of solar cells close to the user on free surfaces, e.g., the roofs of houses, are said to be sufficient for hydrogen production [390].

Indirect Solar Energy. Solar radiation leads indirectly to energy potentials on the earth; these have been used by mankind for thousands of years to produce energy.

Water power is utilized at sites distant from private industrial consumers to produce hydrogen for ammonia production (Norway, Egypt, India, etc.). Hydrogen is produced by means of alkaline electrolysis (see Section Principles). An overview of the worldwide utilization of water power is given in [391] and, with respect to the utilization for hydrogen production, in [392]. According to this, the potential hydroenergy of 14 700 TWh/a worldwide is utilized at present to ca. 15 %. However, the greatest unused potential lies in zones far away from population and industry, such as the Arctic, Greenland, Alaska, Sibiria, or in the equator zones (Congo) [393]. About 30 % of the additional potential could be used for hydrogen production [392]. On the other hand, too great a utilization of the hydroenergy potential meets with ecological disapproval because of the destruction of the landscape by dam-building, flooding of large areas, destruction of forrests, etc.

Wind energy is used on islands to satisfy local energy requirements and to feed power into the grid. Pilot plants for the production of hydrogen already exist (see Section Future Developments). The coastal regions are particularly suitable for the generation of wind energy. Areas with particularly high wind speeds and low energy requirements which could be used for overregional production of hydrogen energy are Patagonia (South America), Somalia (Africa), and the Southwest Australian coast.

Biomass, Refuse, Wastewater. Hydrogen can be recovered from these substances by various methods.

The direct production of hydrogen by means of bacteria is possible; yields of up to 20 % have been attained (see Section Hydrogen Formation in Biological Systems). Other possibilities are the biological production of alcohols or methane from biomass or refuse by fermentation or other anaerobic processes. These substances can be converted by the methods described in Section Production from Coal and Hydrocarbons into hydrogen. Synthesis gases or hydrogen can be produced from biomass and refuse by pyrolysis or gasification processes analogous to those described for fossil feedstocks (see Section Production from Coal and Hydrocarbons).

The hydrogen production potential from biomass, refuse, or wastewater is not considered to be very high for various reasons. Firstly, other valuable products and energy carriers, such as edible products, alcohol and methane, can be produced directly from the substances. Secondly, these sources are usually widely distributed, so that for a central industrial hydrogen economy the costs for transport and logistics would be very high.

Nuclear Energy and Other Energy Forms. Nuclear energy has also been suggested for the production of hydrogen [394], [395]. Various types of conventional and breeding reactors can supply power for hydrogen production, whereas the high-temperature reactor supplies heat for chemical reactions. The direct production of hydrogen by means of radiolysis (see Section Thermolytic and Radiolytic Processes) is an undesired accompanying phenomenon in pressure and boiling water reactors.

Other energy forms, such as *geothermal* or *tidal energy*, play a marginal role in the energy production. They need not be considered for the hydrogen energy concept.

A combined utilization of nuclear energy and fossil, nonconventional resources has been sugggested for the tar sands in Canada, for oil shale deposits in the United States, and for the heavy oil found in Venezuela. Hydrogen and steam are thereby cogenerated. Steam is used for the recovery of hydrocarbons and for processing, hydrogen is used for the hydrogenation of heavy oil.

9.2.2. *Production Methods for the Energy Carrier Hydrogen*

The conventional methods described in Sections Production from Coal and Hydrocarbons and Electrolysis as well as Chapter Purification of Hydrogen are available for the purification and production of hydrogen for the hydrogen energy scenario.

Purification Methods. The purification requirements for the hydrogen energy economy depend not so much on the planned utilization as on the hydrogen storage technique and transport (vectorization). The highest purity is necessary if hydrogen is liquefied, because all impurities, apart from helium, are deposited as solids and could block the liquefication equipment.

Storage and transportation in metal hydrides also place high requirements on the hydrogen purity, because most impurities lead to irreversible destruction of the storage material. Purity requirements are less for the direct combustion of hydrogen and the reaction with oxygen or air in fuel cells. All purity requirements can be met using conventional technologies, particularly adsorption (see Section Adsorption Processes).

Electrolysis. The most important hydrogen production method for the hydrogen energy scenario is electrolysis (see Section Electrolysis). Here, the energy carrier electricity is converted to the energy carrier hydrogen. Conventional electrolyses have a conversion efficiency of 80 – 85 %. Improved electrolyses are expected to have an efficiency of 88 – 94 % [396], which can hardly be increased further. In the high-temperature electrolyses at present under development, however, part of the energy necessary for the electrolysis can be supplied as thermal energy and it can therefore produce hydrogen with a higher efficiency than with solely an electrical supply.

The combination of regenerable energy forms, such as photovoltaic or wind energy with electrolysis units has undergone a long-term test in pilot projects (see Section Future Developments). In addition, detailed system analyses have been made [397]:

electrolysis and thermal solar power plants (power generator can be driven by steam or a Stirling motor),
electrolysis and thermal solar power plants, coupled with high-temperature electrolysis [398],
electrolysis and wind energy,
electrolysis and photovoltaic plants.

Particular problems with the electrolysis are caused by the fluctuating operation of the solar plant cycle at various times of the day as well as weather-dependent fluctuations of solar and wind energy.

Typical problems caused by *rapid* load changes:

degradation and destruction of diaphragm because of local overload,
corrosion caused by current leakages, and
deactivation of the electrode catalysts

Problems caused by *slower* (daily) changes:

cooling of the electrolysis module,
mixing of gas and electrolyte,
pressure equalization between cathode and anode, and
start-up and shut-down procedures including eventual prepolarization or blanketing.

Additional Methods of Hydrogen Production. Additional methods are:

1. Hydrogen production by means of thermochemical cycle processes using thermal energy (solar or nuclear energy)
2. Hydrogen production by *gasification* of refuse or biomass (for process principles see coal or heavy oil gasification, Section Gasification of Coal and Hydrocarbons)

3. Hydrogen production by *pyrolysis* of refuse or biomass (for gas purification see coke oven gas treatment, Section Coke Oven Gas).

For technical and economic reasons the aforementioned methods play only a small part in the production of hydrogen for energy systems.

9.3. Hydrogen-Energy Conversion Systems

For utilizing the energy contained in the secondary energy carrier hydrogen, numerous techniques are available, in the area of energy technology in industry and household, in power stations and in the transportation sector. Most of these are based on principles which have been known for a long time. Section Hydrogen-Energy Conversion Systems gives an overview of the state of the art and of present developments world-wide.

9.3.1. *New Developments for Hydrogen Storage*

The possibility to store hydrogen amounts to the possibility to store energy; this is the particular advantage of a secondary energy carrier. In addition to storage in the gaseous or liquid state (Section Storage) there are numerous investigations or experimental applications of new processes for hydrogen storage in solids.

9.3.1.1. *Cryoadsorption*

Great quantities of gaseous hydrogen can be adsorbed on suitable adsorbents at medium pressure and low temperature. If the adsorber is cooled to 60 – 100 K and pressurized to ca. 4 MPa, the *average* hydrogen density on the active surface increases to values comparable to the density of liquid hydrogen. The *effective* storage density is, however, much smaller because part of the volume is taken up by the adsorbent and the pressure vessel; however, liquefaction can be avoided.

The process has been investigated experimentally [399], [400]. Only materials which are light and very porous, with a high specific surface or with a specifically activated surface can be used as adsorbing agents. Operating data for a cryoadsorption storage system on the basis of activated carbon bulk density 0.35 g/cm^3 are listed below:

Temperature range for isothermal operation	65 – 70 K
Charge-discharge pressures	0.2 – 4.2 MPa
Storage density of hydrogen (75 K and 4.2 MPa)	68 g H_2 per kilogram adsorbent
Maximum hydrogen storage density (65 K and 4.2 MPa)	82 g H_2 per kilogram adsorbent
Average mass related storage capacity	50 g H_2/kg
Average volume related storage capacity	15 g H_2/L

The economic range for the technical application will presumably be limited to medium-scale storage with a specific storage capacity of 20 – 30 kWh/kW.

9.3.1.2. *Hydride Technology*

The capability of metals or metal alloys to reversibly store hydrogen in the form of hydrides has lead to a great number of investigations with respect to technical applications. The main areas are seen in the storage of hydrogen but also in the separation of hydrogen from gas mixtures, the purification of gases, and in storage and separation of hydrogen isotopes. An overview is given [401][402][403][404].

Physical Fundamentals. Ionic and metallic hydrides are formed (exothermic process) and decomposed (endothermic process) according to

$$y\mathrm{Me} + x\mathrm{H_2} \rightleftharpoons \mathrm{Me}_y\mathrm{H}_{2x}$$

The hydrogen absorption and hydride formation behavior can be described by pressure – composition isotherms (see Fig. 102 A) as follows. After catalytic dissociation of the hydrogen molecule some of the atoms lose their electron and occupy an interstitial position in the crystal structure of the host metal (solid solution, α-phase). As the hydrogen concentration is increased, local H – H interaction causes nucleation which induces growth of the hydride phase (β-phase). The two phases ($\alpha + \beta$) coexist until, through further hydrogen uptake, the stoichiometric limit is reached. Here, the isotherms reach a plateau level (constant pressure) which is given the name ‘dissociation plateau' or ‘plateau pressure'. After the pure β-phase is reached, any further increase of the hydrogen : metal ratio requires a steep increase in hydrogen pressure. At higher hydrogen pressure further plateaus may be found because of the existence of other hydride phases (γ, δ, . . .).

Figure 102. A) Ideal pressure-composition isotherms for a hydrogen-metal system

B) Absorption and dissociation isotherms of $LaNi_5$ hydride with hysteresis

C) Hysteresis loops of test cycles of FeTi at 25 °C. The plateau pressure of the monohydride stabilizes after ca. 20 cycles, whereas that of the dihydride formation is still rising

D) Pressure-composition isotherms of hydrogen and deuterium in zone-refined vanadium at 40 °C

On reducing the hydrogen pressure the process is run through in the reverse direction (desorption isotherm). Along the desorption plateau, the hydride phase decomposes into hydrogen-saturated metal and hydrogen gas. The decomposition process is endothermic. Absorption and desorption isotherms show a hysteresis effect. This is shown in Figure 102 B and C for $LaNi_5$ and FeTi [405], [406].

The plateau pressure *p*, which varies strongly with temperature, is connected with the formation or decomposition enthalpy by the Van't Hoff equation. The entropy term, ΔS^0, consists mainly of the standard entropy of gaseous hydrogen ($S^0[H_2^g]$ = 130.6 J mol^{-1} K^{-1}), because the entropy of the hydrogen dissolved in the metal can be neglected.

$$-RT \ln p_{H_2} = \Delta H - T\Delta S$$

$$\log p_{H_2} = \frac{\Delta H}{19.14\,(T/1000)} + 6.82$$

This relationship can be illustrated graphically for all hydrides and for the corresponding hydride transition steps (hydride isochores) (see Fig. 103). Applications can be found in a temperature range from –30 – 300 °C and at pressures up to 10 MPa.

Figure 103. Hydride isochores for various metals and intermetallics. H_2-plateau dissociation pressure vs. 1/T

Mm denotes mischmetal, an inexpensive mixture of rare earths

The heat evolved by the hydrogen – metal reaction depends on the type of hydride. It can amount to ca. 30 % of the heat of combustion of the absorbed hydrogen. To liberate hydrogen, at least the same amount of energy is required (see Table 43).

Table 43. Comparison of the hydrogen absorption data of some metal – metal hydride systems

Hydride system	Heat of reaction, kJ per mole H_2	Plateau region [a]		Hydrogen content		Energy density,[c]
		pH_2, MPa	*T*, °C	wt %	g/mL [b]	kJ/g
Elemental metals						
Mg – MgH_2	77.4	0.1	286	7.7	0.107	9.9
Ti – TiH_2	124	0.1	650	4.0	0.15	5.7
V – VH_2		0.4	40	2.1	0.19	2.95
Alloys						
Mg_2Ni – Mg_2NiH_4	64.5	1.0	350	3.16	0.081	4.5
FeTi – $FeTiH_{1.95}$	31.4	0.5	30	1.72	0.096	2.5

$LaNi_5$– $LaNi_2H_{5.9}$	30.2	0.5	60	1.37	0.089	1.95
$Ti_{0.98}Zr_{0.02}V_{0.43}Fe_{0.09}Cr_{0.05}Mn_{1.5}$		1.0	24	1.75	0.09	2.5

Intrinsic Properties of the Hydride-Forming Materials. To analyze the utilization possibilities of hydride-forming metals, some further properties, some of which are crucial, must be known. The overall kinetics of hydride formation, e.g., is governed by the intrinsic kinetics (dissociation, surface penetration, diffusion, phase transformation), heat flow, and mass flow. In particular, surfaces of *intermetallic compounds* containing transition metals accelerate the dissociation reaction, whereas thin *oxide layers* on the surfaces of elemental metals often block this. Easy hydrogen sorption is facilitated by surface segregation with continuous formation of reactive subsurfaces (self-activation). Addition of small quantities of transition elements, e.g., nickel, will always favor activation. Impurities in the hydrogen, such as carbon monoxide, hydrogen sulfide and sulfur dioxide slow down the *sorption rate* because of surface deactivation, whereas oxidizing impurities, such as oxygen and water, gradually *decrease the capacity* by reaction with the host compound. Such “poisoning” of the hydride material can in many cases by reversed by hydrogenation – dehydrogenation cycles with pure hydrogen at higher temperature.

Diffusion is normally not the rate-determining step because most of the hydride-forming materials disintegrate into powder with a grain size down to 1 µm.

Incorporation of the hydrogen into the lattice and the α/ β-phase transition causes a deformation of the metal structure. The accompanying increase in volume can amount to 25 % and may lead to undesired distortion of the containing vessel.

Detailed analyses of the kinetics of hydride formation of $LaNi_5$ and MgNi are available [407]. For most hydride-forming systems using intermetallic compounds, heat transfer is rate-controlling. Sufficient heat transfer can be provided by adding inert metals (Cu, Al) or inert ceramic beads or by pressing the material into pellets to fit into heat exchanger tubes.

Hydride-Forming Materials. The criteria for selection of a material for a specific application are:

- high adsorption capacity
- suitable temperature and pressure range
- sufficient exchange rate
- long-term stability
- long cycle life

In the temperature range from –20 – 400 °C the following groups of alloys are known:

- – 20 – 100 °C
  - AB_2 alloys, e.g., $ZrMn_2$
  - AB_5 alloys, e.g., $LaNi_5$
  - FeTi-based alloys
- 300 – 400 °C
  - Mg and Mg-based alloys

Some metal – metal hydride systems and their important properties are summarized in Table 44. In recent years development has concentrated on cheaper multicomponent alloys and modeling materials to optimize uptake and storage parameters. About 10 different storage alloys are commercially available from producers in Europe, Japan and the United States at prices between $ 5 and 30 per kilogram.

Table 44. Hydrogen content of fuel gases and corresponding energy content

Fuel gases	H_2 content, %	HHV, kJ/m^3 (STP)	LHV, kJ/m^3 (STP)
Natural gas, rich gas	up to 12.5	25 000 – 39 800	35 800 (CH_4)

Town gas	40 – 60	16 700 – 20 000	
Coke oven gas	50 – 60	20 000 – 23 000	16 500 – 20 500
Water gas	50	10 500 – 12 200	10 700 – 11 700
Producer gas, blast furnace gas	2 – 5	4 300 – 4600	3 900 – 4700
Carbon monoxide		12 650	12 650
Hydrogen	100	12 760	10 800

Stationary Hydride Storage. For the stationary storage of hydrogen by using hydrides, FeTi or TiVFeMn alloys can be employed. A representative example for the many developments in this field is the hydride storage vessel of Gesellschaft für Hydrid- und Wasserstofftechnik (HWT). Figure 104 shows a module which consists of a bundle of pressure vessels containing the powdered metal alloy between fins. A sintered metal filter prevents the loss of powder. The gas bundle is surrounded by the heat transfer medium, water. The essential operating data are:

hydrogen capacity	1700 – 2000 m^3 (STP)
active storage material	10 t
operating pressure	5 MPa
operating temperature	80 °C

Figure 104. Hydride storage tank

a) Storage tube; b) H_2-guide tube; c) Lamella; d) Hydride; e) Filter (sintered metal); f) Gas-collecting tube; g) H_2 connection; h) Water inlet (module); i) Water outlet (module); j) Filling body; k) Shell; l) Water inlet (centr.); m) H_2 inlet/outlet (centr.); n) Container

Hydrogen used to fill the vessel should have at least 3.0 (99.9 %) purity. Hydrogen with a purity of 6.0 (max 1 ppm [mL/m^3] impurity) can be drawn off [408].

Mobile Hydride Storage. Possible applications for the hydride storage technology are mobile storage vessels for the laboratory or for hydrogen-fueled cars (see Section Hydrogen Fuel Systems). Figure 105 shows a hydrogen laboratory storage vessel and the corresponding ab- and desorption curves. These vessels are available for hydrogen quantities of 1 – 5 m^3 [409]. In addition to the small space requirements, they offer further advantages such as safe handling, purification effect and availability at higher pressure levels.

Figure 105. Hydrogen laboratory storage vessel and the pertaining adsorption and desorption curves

A) Schematic of a storage vessel; B) Loading at 0.5 MPa, water cooling at 20 °C; C) Unloading against 0.1 MPa, heat exchange medium is water at 80 °C

The energy density of hydride storage systems, including the vessel material, is in the range of 300 Wh/kg for the so-called low-temperature hydrides.

Separation of Hydrogen Isotopes via Hydride Formation. Some metals and alloys (TiNi, Ti_2Ni, V) show considerable differences in the plateau pressure of their hydrides and deuterides (see Fig. 102 D). This can be used for the enrichment of deuterium in deuterium-containing hydrogen streams [410]. The recombination of H and D atoms can lead to the formation of HD. The separation of tritium over vanadium monohydride in a temperature-swing process has been described [411].

Purification of Gases. Hydride-forming materials can be used to purify hydrogen as well as noble gases. Various mechanisms are thereby involved: oxygen, carbon dioxide, and water are removed by

the hydride material because of its getter properties. Carbon monoxide is converted to methane, which is more easily removed, whereas inert gas components, such as the noble gases, can be removed by a short purging step. The hydrogen, which can then be recovered from the hydride bed, has a purity of >7.0, i.e., impurities content <0.1 ppm (mL/m^3) (see Section Quality Specifications).

Hydrogen Recovery. The selective removal of hydrogen by means of hydride-forming metals can be used to separate hydrogen from a gas mixture. The feasibility of this method for recovery of hydrogen from the purge gas stream of an ammonia synthesis loop was demonstrated in a pilot plant. The unit operated with three absorber columns and produced hydrogen with a purity of 99 % and a recovery rate of 90 – 93 % of the hydrogen contained in the purge gas [412]. The process is adiabatic, the heat evolved during absorption is stored in the $LaNi_5$ hydride pellets, which contain a certain amount of ballast material. This stored heat is used for hydrogen desorption. The hydrogen uptake and liberation is pressure-controlled (adiabatic pressure-swing process). The complex dependency of the hydride bed lifetime on alloy type, trace components in the gas, poisons, and various combinations thereof has prevented commercial utilization until now [413].

Thermochemical Machines. Metal hydrides are promising materials for use in thermochemical machines such as heat pumps, heat transformers, refrigerators or hydrogen compressors. The principle is based on thermodynamic cycles in a closed system; a heat pump cycle is shown as an example in Figure 106. The equilibrium lines in the ln p – 1/T diagram are based on measurements of pressure – composition isotherms. The required heat output is assumed to be at 40 °C. Taking into account the different material imperfections (i.e., hysteresis, plateau slope) and the pressure drop necessary to drive the reaction, the level of the low-temperature heat source changes from 2.5 °C (ideal case) to 16.5 °C, while the level of the high-temperature source rises from 82 °C to 103 °C. An advantage is that hydrogen is handled in a closed loop without the risk of contamination. More than 10 developments are being followed up worldwide (United States, Federal Republic of Germany, Japan). The planned applications are in household heating, air-conditioning, refrigeration and power generation. The investigations concern reaction bed designs, flow of the heating or cooling media, heat transfer, etc., using fast-reacting alloys of $LaNi_5$, $LaNi_{4.9}Al_{0.1}$, FeTi for the low-temperature range and $CaNi_5$, Mg_2Ni, $LaNi_{4.7}Al_{0.3}$ for the high-temperature range [414].

($LmNi_{4.8}$ is a lanthanum-rich mischmetal)

Compression of Hydrogen. Hydrogen can be compressed thermally by absorption at low and desorption at higher temperature. A machine working on this principle as an open system with several stages is commercially available [415].

9.3.1.3. *Liquid Organic Hydrogen Carriers*

With the help of hydrogenation – dehydrogenation reactions it is possible to store hydrogen reversibly in a chemical compound. The combinations benzene – cyclohexane and toluene –methylcyclohexane have been investigated using noble metal – aluminum oxide carrier catalysts for the reversible reaction. Transportable hydrogenation – dehydrogenation systems operating at 380 – 500 °C and 1.1 MPa have been designed for a truck using hydrogen fuel; the necessary energy for the exothermic dehydrogenation reaction is taken from the exhaust gas of the engine. A specific energy density of 56 g hydrogen per liter liquid hydrocarbon is attained, but the weight of the necessary equipment must be taken into account [416].

The reversible uptake of hydrogen in liquid organic substances has also been suggested for transcontinental hydrogen transport. Existing facilities for gasoline could be used [417].

9.3.2. *Combustion and Heating*

The energy contained in the hydrogen can be released most simply by combustion with oxygen or with air. Characteristic combustion data are given in Chapter Properties.

Hydrogen Content of Fuel Gases. Hydrogen mixtures have long been used in the form of town gas for heating purposes. Table 44 shows the hydrogen content of some fuel gases. The difference between LHV and HHV (condensation enthalpy of water formed during combustion) is greatest for pure hydrogen, because water is formed as the only product.

Emissions. Since only water is obtained as a product of the combustion, emissions, such as carbon monoxide, sulfur dioxide, incompletely combusted hydrocarbons, particles, soot, ash, which are obtained by combustion of fossil fuels, are avoided (see Section Production Systems for Hydrogen Energy for a discussion of the carbon dioxide problem). If hydrogen is burned in the presence of air, the high temperatures favor the formation of nitrogen oxides. The NO_x formation depends on the flame temperature and can be influenced by the value of excess air, λ. Figure 107 shows typical NO concentrations for a hydrogen – air flame. Maximum NO formation occurs in the range of the stoichiometric hydrogen – oxygen ratio, whereas under lean conditions (excess air) low nitric oxide concentrations may be attained [418].

Figure 107. NO concentration resulting from hydrogen – air flames as a function of excess air value λ

($[NO]_e$ = equilibrium concentration; $[NO]_5$ = concentration behind flame front within 5 ms; p = 3.2 MPa)

Hydrogen Burners. Differences in combustion properties, i.e., flame speed and flame stability as well as density and heating value, make it necessary to use a different burner geometry when hydrogen or hydrogen-rich gases are to be burned. The flame speed of hydrogen – air mixtures is seven times higher than that of methane; the particular problem is therefore the flash-back over a wide range of hydrogen – primary air mixtures.

The most important criteria for household burners are summarized, e.g., in [419]. The ratio of secondary to primary air must be increased, if hydrogen is used. Forced draft burners for heating systems can be retrofitted by removal of the baffle plate and by shortening the ignition electrodes [420]. Industrial hydrogen burners are used for heat, steam, and electrical power production. The state of the art are premix burners or nozzle-mix burners with high mixture velocities. For supplying heat in certain industries (semiconductors, glass) the simultaneous presence of a reducing atmosphere is advantageous.

Catalytic Combustion. The thermal energy of hydrogen can also be released by means of flameless catalytic combustion. Suitable catalysts, apart from platinum and palladium which initiate reaction at room temperatures, are metal oxides, such as MnO_2 – CuO – Ag_2O (Hopcalite) or Co_3O_4. The surface can be enlarged accordingly by a suitable carrier material in the form of porous plates or honeycombs. Catalytic burners operate either on the diffusion principle or by premixing hydrogen with air. Figure 108 shows a catalytic diffusion burner. An overview of Japanese investigations is given [421].

Figure 108. Catalytic diffusion burner

a) H_2 entrance port; b) Electric ignition wire; c) Distribution manifold; d) Catalytic combustion zone; e) Oxygen from air; f) Heat radiation

Catalytic heaters react very flexibly; the temperature can be adjusted and limited by means of the throughput; the heat is produced in the infrared range. The combustion is free of emissions. Since no stacks are required, almost 100 % of the heat set free can be utilized. In addition, the moisture content of the air can be regulated by the reaction product, water.

Transport to Small Consumers. Hydrogen could be distributed via present nets to industrial and household consumers and could substitute natural gas. The energy transport capacity of such a low-pressure network (ca. 10 kPa) leads to about the same heat flux for hydrogen as for natural gas.

9.3.3. *Hydrogen Fuel Systems*

In all sectors of transportation (space and aircraft propulsion, earthbound traffic systems including individual transport) the fuel systems hydrogen – air or hydrogen – oxygen can be used for the prime mover.

9.3.3.1. *Hydrogen Propulsion Systems for Space*

Because of the large specific enthalpy of combustion LH_2, combined with liquid oxygen (LOX), produces (apart from the system LH_2 – LF_2) the greatest specific impulse. Jet velocities up to 4500 m/s can be reached using combustion chamber pressures of 5 to 22 MPa.

The hydrogen – oxygen motor NASA Centaur (Pratt & Whitney) was used for the third stage of the Atlas Centaur and the fourth stage of the Titan III rocket. For the Apollo project Rocketdyne motors were used for the second and third stage of the Saturn V [422]. The peak of the US development is the Space Shuttle main engine, a high-pressure motor with a combustion chamber pressure of 21.5 MPa.

The European Ariane carrier system uses LH_2 – LOX in its third stage. Using 10 t of this fuel combination, the HM7 motor develops a thrust of 60 kN over a period of 700 s. A further development for 800 kN thrust and a fuel requirement of 120 t with the designation HM60 is being developed [423].

9.3.3.2. *Hydrogen as Aviation Fuel*

In the future the following alternative aviation fuels will be available:

- jet fuel “aviation grade” from coal (Synjet)

liquid methane (LCH_4)
liquid hydrogen (LH_2)

Liquid hydrogen has already been tested in 1957 in a B 57 Canberra by the NACA Lewis Research Center (Cleveland, Ohio) and its suitability as an aviation fuel was proven. Since 1973, especially in the United States, investigation of the use of LH_2 as an aviation fuel has been follwed up (overviews [424-426]). In 1988, test flights were made in the Soviet Union with a civil aircraft using LH_2 as fuel.

Hydrogen is suitable for turbines in the sub- and supersonic regions. Engine designs for turbines converted to hydrogen fuel have certain advantages: They are smaller, easier to control and have a longer lifetime than normal turbine fuels. The cryogenic fuel is used to cool engine oil and turbine cooling air, whereas the turbine core exhaust heats up the fuel before injection into the combustor. The savings in the specific fuel consumption amount to 8 %. Ecological benefits are the lower noise level, smaller emission of NO_x, and absence of CO, CO_2, and hydrocarbons.

The energy content related to volume and mass of LH_2 is the determining factor for the construction of a hydrogen aircraft. The four times greater fuel volume as compared to hydrocarbons for the same energy content and the cryogenic properties require a completely new concept for the aircraft fuselage and tanks. To minimize surface – volume ratio, the insulated tanks are placed both fore and aft of the passenger compartment. Weight advantages are gained by tank configurations which are integrated in the aircraft fuselage structure. For the complicated aircraft fuel system three absolutely equivalent fuel booster pumps per tank compartment are foreseen [427].

The 2.8 times higher energy content of LH_2 compared to kerosene (related to mass) makes it possible to have a much smaller lift-off weight for the same range and capacity. A comparison of design data and various performance characteristics of subsonic aircrafts for the fuels listed is shown in Table 45.

Table 45. Comparison of design and performance data of alternate fueled subsonic aircraft (basis: 400 passengers, 44 000 kg payload, 5500 NMi range, 0.85 Mach cruising speed)

	Liquid hydrogen (LH_2)	Liquid methane (LCH_4)	Synjet
Gross mass, kg	168 830	225 570	232 060
Block fuel, kg	21 620	58 980	72 530
Operating empty mass, kg	103 300	116 170	107 370
Wing area, m^2	296.8	385	380.3
Span, m	51.8	58.9	58.5
Fuselage length, m	65.7	61.4	60
Gross mass, kg	156 130		
Block fuel weight*, kg	15 270		
Specific fuel consumption (cruise), kg h^{-1} N^{-1}	0.206	0.504	0.615
Lift/drag (cruise)	17.4	19.21	19.13
Thrust per engine, N	135 000	177 000	185 000
Energy utilization, kJ $seat^{-1}$ km^{-1}	636	723	759

* with respect to laminar flow control.

Similar studies have been presented for LH_2-fueled supersonic aircraft. Here the immense fuel requirements are even more in favor of LH_2. A comparison shows a reduction in the lift-off weight by ca. 50 %.

Laminar Flow Control (LFC). The cryo-fuel LH_2 makes it possible to use the so-called *cryogenic wall cooling* technology. By cooling major aerodynamic surfaces of the aircraft to ca. 150 K, laminar flow in boundary layers is stabilized with a consequent reduction of skin-friction drag. The necessary refrigeration can be taken from the evaporating LH_2 directly or via a secondary refrigeration system (e.g.,

LN_2). Overall drag reduction in the order of 20 % leads to a fuel saving of about the same amount at cruising speeds [428].

Airport requirements for LH_2 as fuel have been investigated in different studies. The facilities include the liquefaction plant, LH_2 storage capacity and LH_2 fuel handling systems [429], [430]. Because of planning and development issues, the use of LH_2 as an alternative fuel for aviation will not occur before the next two aircraft generations, i.e., about 2030.

9.3.3.3. *Hydrogen for Automotive Vehicle Transport*

Mobile Otto and Diesel internal-combustion engines for vehicles can be operated on hydrogen or hydrogen – gasoline mixtures. RICARDO (1924) and BURSTALL (1927) carried out some of the first investigations. In 1930, ERREN made intensive studies on hydrogen – air and hydrogen – oxygen motors. The first internal-combustion engine car in the United States fueled by hydrogen was presented by BILLINGS in 1966 in Utah. At the moment further developments are in the Federal Republic of Germany, Japan, Australia and the Soviet Union. The literature on this topic is abundant. Overviews are given in [431-433].

Modification of the Engine. Some properties of hydrogen make engine modifications necessary; low ignition energy and high flame speeds can cause self-ignition during the mixture preparation or flame flash-back. The octane number of hydrogen is much lower than that of gasoline. However, the wide ignition range allows burning of lean mixtures and gives a large control range.

Various techniques are used to prepare the feed mixture to the combustion chamber. With *external mixing* a homogeneous hydrogen – air mixture is introduced. Uncontrolled preignition or flash-back into the intake manifold is prevented by adding ballast, preferentially water, and by timed individual port injection of hydrogen close to the cylinder intake. *Internal mixture* formation is achieved by direct injection into the combustion chamber. The necessary supply pressure must be at least 1.5 MPa, or even, depending on the time of injection, more than 10.0 MPa. This is only possible by using piston pumps for liquid hydrogen. Figure 109 shows the principle layout of internal and external mixture formation.

Figure 109. Internal mixture formation (A) using cryogenic hydrogen (direct injection) and external mixture formation (B) using ambient-temperature hydrogen

Attainable specific charge heating values (energy content per cylinder loading) are compared in Table 46 under various operating conditions. Revolutions per minute (rpm) and effective efficiencies are comparable to the gasoline motor. Because of the lower air quantities possible and the lower heating value of the mixture, *external mixture* formation with water injection gives power ratings comparable to that of Diesel motors, whereas with internal mixtures ca. 40 kW/L cylinder volumes can be attained [435].

Table 46. Specific charge heating values of hydrogen – air mixtures in combustion engines compared to gasoline

Operating conditions	Maximum of spec. charge HV $H_{spec.\ max}$		Maximum of efficiency $\eta_{e\ max}$		Maximum of excess air φ_{min}	
	φ	kJ/L	φ	kJ/L	φ	kJ/L
Gasoline	1	37.7	1.1	34.4	0.83	31.6
Hydrogen (external mixture formation)	1	31.9	0.4	15.5	0.2	8.3
Hydrogen (internal mixture formation)	1	45.3	0.4	18.1	0.2	9

Hydrogen-powered engines emit only water and NO_x. Numerous investigations concerning the calculation and measurement of the nitric oxide emission have been carried out, e.g., [436], [437]. In Figure 110 typical NO_x values for various modes of operation with hydrogen and gasoline are shown as a function of the equivalent ratio ($\varphi = l/\lambda$). Especially in lean modes of operation, i.e., with excess air, hydrogen motors operate more or less emission-free.

Figure 110. Typical NO_x values for various modes of operation of hydrogen (a – d) and gasoline engines

a) External mixture formation, load governing; b) External mixture formation, quality governing; c) External mixture formation, optimum attainable values; d) Internal mixture formation; e) Typical values for Otto and Diesel engines

On-Board Hydrogen Storage. At present three storage possibilities can be considered:

in the gaseous state in pressure vessels,
in the liquid state in vacuum-insulated tanks, or
chemically bound in metal hydride storage tanks.

Table 47 compares various mobile storage methods for vehicles. It is clear that none of the hydrogen storage systems have reached the undoubted advantages of the fossil energy carrier, gasoline.

Table 47. Comparison of mobile storage systems for hydrogen (basis: 45 m^3 H_2 corresponding to 15 L gasoline)

	Liquid H_2	Gaseous H_2	Metal hydride-H_2
Hydrogen content	57 L	45 m^3	4 kg
Gross storage mass, kg	20	2×60	320
Hydride material, kg			220
Maximum operating pressure, MPa	0.4	30.0	5.0
Operating temperature, °C	–253	–20 – +50	–20 – 100
Energy densities,			
kWh/kg*	6 – 7	1.1	0.4
kWh/L*	0.95	0.55	0.8

* Energy density of a gasoline tank: 8 – 8 kWh/kg (8 – 9 kWh/L).

Pressure gas storage vessels are disadvantageous because of their large weight and volume. The high storage pressure of ≥ 20.0 MPa raises safety and supply questions.

Liquid hydrogen tanks for vehicles are larger than gasoline tanks and require a complicated construction because of the low storage temperature. Characteristic data for a tank in the boot of a car (BMW-DFVLR experimental vehicle) are [434]:

double-walled cryo-vessel for 45 L of hydrogen,
vacuum superinsulation cooled by means of evaporating hydrogen,
mass (filled) of 45 kg,
operating pressure 0.2 MPa, lowest operation temperature –253 °C,
evaporation losses <2 %,
hydrogen delivery pressure via LH_2 piston pumps 1.5 – 2.0 MPa.

Problems exist concerning the evaporation rate, safety questions and tanking techniques. Tanking of the test vehicles occurred at a computer-controlled, half-automatic LH_2 station, so that maloperation was avoided. The tanking time was ca. 5 min.

Mobile hydrogen *hydride storage vessels* are used for example in Daimler Benz test vehicles. For details of the hydride technology see Section Hydride Technology. Suitable hydride-forming metals are those, in which reversible hydrogen absorption occurs in the temperature range of –25 – 100 °C. These are *low-temperature* hydride materials, such as FeTi. *High-temperature* hydride materials, such as Mg_2Ni, have a higher capacity, but more energy at 350 °C is required to drive off the stored hydrogen. Figure 111 shows a hydride tank using a titanium – vanadium – manganese alloy for a vehicle.

Addition or removal of heat is performed by a heat carrier, such as a water – defrosting agent mixture connected externally during tanking or internally during operation of the vehicle. With a full storage vessel the minimum pressure of 0.2 MPa required to start the motor even at –20 °C is available [438]. High-purity hydrogen (99.999 %) must be used to avoid a passivation of the active material. A quick tanking operation with gaseous hydrogen at 5.0 MPa takes ca. 10 min.

Figure 111. Hydride storage tank for motor vehicle drives of HWT

a) Storage tube; b) H_2-guide tube; c) Lamella; d) Hydride; e) Filter (sintered metal); f) Gas-collecting tube; g) H_2 connection; h) Water inlet; i) Water outlet; j) Filling body; k) Vent valve connection; l) Shell

The motor concept chosen for a vehicle depends on the method of storing the hydrogen on board. Low-pressure gaseous hydrogen allows only external mixture formation, whereas liquid hydrogen, because of its cryogenic properties, is more flexible (liquid compression, cooling, injection).

State of the Art. Representative for the many investigations being carried out in several countries, two development projects in the Federal Republic of Germany are described:

Between 1984 and 1986 Daimler Benz tested a fleet of 10 hydrogen vehicles under normal operating conditions in Berlin. Delivery vans (Fig. 112) were equipped with a 2.3 liter spark-ignition engine with external mixture formation and water injection and a power of ca. 77 kW. Hydrogen storage was by four low-temperature, liquid-heated hydride storage units with a total mass of 560 kg and a hydrogen capacity of 66 m^3. This was sufficient for a range of 120 km in city traffic. The total mileage for the entire fleet amounted to 160 000 km [439].
Deutsche Forschungsanstalt für Luft- und Raumfahrt (DFVLR) has been working with BMW since 1979 on vehicles with LH_2 tanks and different approaches for the mixture formation. The present state of development is the 745i Sedan with a 3.5 liter spark ignition engine with a so-called “late internal mixture formation,” i.e., hydrogen injection during the compression stroke. The power output is claimed to be ca. 150 kW [440].

9.3.4. *Electricity Generation from Hydrogen*

Apart from the direct utilization of hydrogen for heating purposes (see Section Combustion and Heating) the generation of electricity is important in the hydrogen energy concept. This can be done indirectly via combined heat – power processes or directly by electrochemical means.

9.3.4.1. *Heat – Power Processes*

Suitable heat – power processes for power generation from hydrogen are [441]:

1. conventional steam turbine processes with hydrogen-fueled boilers,
2. open hydrogen – air gas turbine processes, and
3. hydrogen – oxygen steam turbine processes

The thermal efficiency of various hydrogen-fired power station processes with up to 100 MW power is given in Figure 113 as a function of the range of turbine-entrance temperature t_E. A hydrogen – oxygen power station with condensation attains an efficiency of 52 % at full load. This type of power station (line a) is most suitable for peak-load power production. For immediate increase of power output of fossil-fired ground-load or medium-load power stations a hydrogen – oxygen steam production unit can be integrated (see Fig. 113, line b instantaneous reserve plant).

Figure 113. Thermal efficiency of various hydrogen-fired power station processes

a) Hydrogen-oxygen power station; b) Conventional hydrogen power station; c) Hydrogen power station with gas turbine; d) Hydrogen power station with gas turbine, improved design

A new component suggested for power stations is the hydrogen – oxygen steam producer. An experimental version for a thermal capacity of 15 – 40 MW exists at the DVFLR (Fed. Rep. of Germany). A schematic is shown in Figure 114. Hydrogen and oxygen are introduced through a suitable lance and equally distributed in the combustion chamber before burning. The combustion product, the temperature of which is 3000 °C, is cooled down to the required steam temperature by water quenching and fed to the turbine. It is particularly important to maintain the stoichiometric ratio of the fuel mixture in order to avoid noncondensable gas components (excess oxygen or hydrogen). This is achieved by means of a sophisticated control strategy. Starting from zero, full load can be reached within 1 s (here 40 MW); steam with a pressure of 4.0 – 9.0 MPa and a temperature of 560 – 950 °C can be produced [442].

Figure 114. Schematic of the DFVLR H_2 – O_2 steam producer

a) Injection head; b) Gas distribution; c, d) Injection manifold; e) Combustion chamber; f) Injection rings; g) Radial water injection

9.3.4.2. *Electrochemical Energy Conversion*

In a reversal of the electrolysis process, the chemical energy of hydrogen can be converted directly into electrical energy. This takes place in fuel cells by allowing the “cold” combustion of hydrogen and oxygen to occur electrochemically (⟶ Fuel Cells) [443].

At room temperature the maximum possible voltage of the hydrogen – oxygen system is 1.23 V. In practice, cell voltages of 0.7 V are reached. Since heat – power conversions are avoided, efficiencies of 40 – 60 % can be attained. For details of the mode of operation, electrodes, catalyst materials and construction see [444], [445]. The most developed versions are the *low-temperature fuel cells*, which are usually identified by the electrolyte employed, as alkaline fuel cells (AFC), phosphoric acid fuel cells (PAFC), and solid polymer electrolyte fuel cells (SPEFC).

Alkaline fuel cells are used for power production in space as well as for special applications (relay stations, emergency power supply, military purposes). Without exception, they use pure hydrogen and carbon dioxide-free oxygen and have a low specific mass (7.2 kg/kW) and a long lifetime. They are, however, very expensive (1500 $/kW) [446].

Phosophoric acid fuel cells operate at 200 °C and use hydrogen or hydrogen – carbon monoxide mixtures produced from natural gas and air. The complete unit contains not only the cell modules but also various components, such as utility supplies, systems for temperature control, means to remove product water, and controls for the electrolyte pumping.

High-temperature fuel cells are still in the development stage; *molten carbonate fuel cells* (MCFC) operate at 600 °C and use an alkali-metal carbonate melt as electrolyte. *Solid-oxide fuel cells* (SOFC) contain ceramic ZrO_2 membranes, (solid electrolytes); on these electrolytes hydrogen reacts with air at 800 – 1000 °C. The hydrogen production from methane and steam can be integrated into the cell [447].

Fuel Cell Power Plants. Hydrogen, hydrogen-rich gases, or gases which can be converted to hydrogen can serve as fuel for fuel cell power plants. As depicted in Figure 115, such a facility for district electricity and heat generation comprises three subsystems; a fuel processor, a power section made up of a number of modules and a power conditioner. The suitability of the phosphoric acid fuel cell for this purpose has been proven in the United States in a field test (46 40-kW PAFC units) [449]. In Japan two 1 MW blocks have been built as an alternative energy production to thermal power generation [450].

9.4. Future Developments

Several books and monographs dealing with the perspectives and planning of the utilization of hydrogen as a major universal energy carrier have been published [386], [389], [451-453].

9.4.1. *Production Schemes*

Possible Schedule. The introduction of hydrogen as an energy carrier can be assumed to be governed mainly by economic aspects. The following developments can be expected [454]:

1. *First stage of utilization.* Future hydrogen utilization will be based on current uses of hydrogen, which are mainly nonenergetic. Hydrogen produced from non-hydrocarbon sources (normally from electrolysis) will be introduced to serve similar purposes.
   *Primary energy*will be supplied by nuclear or hydropower stations with energy reserves available during off-peak periods. The economic conditions for electrolytic production of hydrogen are especially favorable in France (nuclear power) [455] and Canada (hydropower) [456].
2. *Special Applications.* The combined production and utilization of hydrogen and oxygen by electrolysis could provide an additional economic impetus. Possible fields of utilization are:
   heavy oil upgrading (hydrogen for hydrogenation, oxygen for residue gasification) [457], [458]
   wood gasification combined with methanol production [459]
   all other kinds of coal, residue, or waste gasification with H_2, CH_4, CH_3OH, etc. as products
   biological process such as aerobic wastewater treatment (oxygen required). Hydrogen together with any methane produced in anaerobic stages, could be used as fuel for power production with gas motors or for a denitrification process.
3. *Introduction as a Direct Energy Supply.* Use of hydrogen will start as a supplement to actual energy markets, addition of up to 10 % hydrogen in natural gas nets or use as a fuel in transportation (city buses, underground/underwater devices, aircraft).
   The *primary energy supply* for the uses in both last sections would be the same as for the utilization as energy off peak power. In addition, wind, water, and solar units, which use electrolytically produced hydrogen for long-term storage would also be used.
4. *Advanced Stage of Utilization.* In countries with high solar radiation intensity but little industry, hydrogen could be used as a means of storing solar energy [460]. The solar radiation is converted into electric power using solar collectors, photovoltaic units, or Stirling motors driven by solar heat.
   First decentralized applications for hydrogen as an energy carrier could be for refrigerating large-scale units and for supplying heat in agricultural and industrial operations.
   Schemes for *supplying* the *total energy* requirements to remote areas by hydrogen have also been suggested, e.g., energy requirements of an island in Alaska supplied via wind energy and hydrogen [461].
5. *Hydrogen-Energy World.* The final goal of a world selfsufficient in energy (that does not depend on fossil resources) is the erection of large solar farms in the sunflooded desert areas of Africa, Asia, and Australia. Countries in these regions could export hydrogen (or electric power) to industrial regions with less sun. For more details see [454, pp. 297 – 304].
   According to this study, an area of 0.14×10^6 km^2 (0.1 % of the land surface of the globe), will be required for the production of 1000×10^6 tce/a. The total surface of suitable areas in desert regions is 0.6×10^6 km^2 which is more than sufficient.
   The material requirements for the construction of a solar farm are also within the capabilities of an industrialized country. This is shown in Table 48 [454, p. 321] for the Federal Republic of Germany. Nickel and silicon are the exceptions, the first because of the limited resources available and the latter because appropriate production technologies still have to be developed. Supply of other key items of solar farms such as solar cell panels, heliostat mirrors, Stirling motors, power generators, and electrolysis units, is also adequate (see Fig. 116) [454, p. 329].

Table 48. Comparison of material requirements for hydrogen plants with the consumption of primary raw materials in the Federal Republic of Germany (1983). Projected annual production of hydrogen plants ca. 155 PJ/a (equivalent to the energy produced by 100 100-MW-units per year, usable ca. 4000 h/a) [389]

Raw material	Annual consumption 1983*, 10^3 t/a	Consumption for production of solar plants, % of annual consumption (1983)			
		Photovoltaic solar cell	Solar tower	Paraboloid mirrors, solarthermic	Wind converter
Steel	26 600	12.7	32.0	24.0	11.8
Aluminum	1085	11.5	16.6	18.4	1.8
Nickel	63	95.2	206.3	135.0	47.6
Glass	1240	126.6	209.0	178.2	6.5
Concrete	210 000	10.6	18.3	21.0	5.0
Silicon	0.36	16 667			

* Annual primary energy use in 1980: World 300×10^3 PJ/a; Western Europe 76×10^3 PJ/a ; Fed. Rep. of Germany 7.6×10^3 PJ/a ; North America 90×10^3 PJ/a.

Figure 116. Comparison of annual production of certain industrial products in the Federal Republic of Germany and the required comparable items for hydrogen plants for the hydrogen energy concept [460]

Projects. Already existing hydrogen projects serve and will serve the following purposes:

1. Demonstration of feasability
2. Study of technical problems occurring during operation under realistic conditions
3. Optimization and coordination of the various systems involved (e.g., mechanical – photovoltaic systems, electronic – photovoltaic systems)
4. Moving from the “tailor-made” stage of the components to a prototype production stage
5. Demonstration of self-sufficiency in terms of energy supply without fossil fuel or nuclear power

Although some individual components of a future hydrogen economy have already been tested (see Section Hydrogen-Energy Conversion Systems), few projects have realized the concept in its entirety from hydrogen production to its utilization. In 1979, R. E. BILLINGS built a house in Independence, Missouri, in which the energy supply, including that for car and tractor, was based on hydrogen. The primary energy was by hydropower, storage by means of metal hydrides and solar energy was used as subsidiary energy for heating purposes.

In Harnøsand, Sweden, O. TEGSTRØM has converted the energy supply of his car and his house, to hydrogen. Wind is used to supply the primary energy via and turbines with 55 kW. Metal hydrides are used for hydrogen storage.

Hysolar [462]. Founded in 1985, Hysolar (a joint venture between the Federal Republic of Germany and Saudi Arabia) foresees the installation of three photovoltaic electrolysis plants: a 100-kW (electric power) plant is to be built in Saudi-Arabia; two plants with 10 and 2 kW at a German and a Saudi Arabian university respectively serve research and demonstration purposes [462].

Solar Hydrogen Bavaria (SWB) is scheduled to go on stream in the Federal Republic of Germany in 1989 [463]. Figure 117 shows a diagram of the plant. Project costs amount to more than 50×10^6 DM (33×10^6 DM for the plant, 12×10^6 DM for personnel, 5×10^6 DM for infrastructure).

Figure 117. Block diagram of the Bavaria Solar Hydrogen Plant (planning status)

a) Photovoltaic cell; b) d.c. Converter; c) Power net; d) a.c./d.c. Converter; e) Electrolysis power supply; f) Electrolysis unit; g) Oxygen purification; h) Hydrogen purification; i) Alkaline fuel cell; j) Phosphoric acid fuel cell; k) Gas heater; l) Gas heater; m) Heat storage

Plant data:

Solar generator – 500 kW_{el} from various modules

Photovoltaic cells: total surface area 7000 m^2

Electrolysis unit:

100 kW_{el} conventional KOH electrolysis

100 kW_{el} zero gap KOH/NaOH electrolysis

80 kW_{el} solid polymer membrane electrolysis

Gas storage:

5000 m^3 (STP) of H_2 at 3 MPa

500 m^3 (STP) of O_2 at 3 MPa

Fuel cells:

6 – 8 kW_{el} alkaline type
80 kW_{el} phosphoric acid type
Catalytic combustion: 4 kW_{th}
Gas boiler: 20 kW_{th}

Euro-Quebec Project [464]. In this study initiated in the Federal Republic of Germany, the transport of hydroelectric power from Canada to Europe by means of hydrogen is being investigated. The Canadian hydropower is converted into hydrogen by electrolysis. The hydrogen is transported in one of three forms: (1) as liquid hydrogen shipped in special tankers (or eventually by aircraft); (2) as liquid ammonia shipped in special tankers; or (3) as methylcyclohexane shipped in oil tankers. The hydrogen is used in Europe for electricity, heat generation, vehicle and aviation propulsion, and hydrogen as an additive to natural gas for domestic or industrial use.

Figure 118 A shows the mass flow diagram developed for Phase I of the study; the energy flow diagram is shown in Fig. 18 B.

Figure 118. Flow diagrams for the transportation of hydrogen from Canada to Europe (Euro – Quebec project). It is planned to transport hydrogen in liquid form or chemically bound as methylcyclohexane (MCH) or ammonia by sea or air

A) Mass flow diagrams (transportation energy is neglected)

B) Energy diagram (in the energy diagram for chemically bound hydrogen only ammonia is shown because MCH is very similar and slightly less effective, η = 0.5 instead of 0.514)

Other Projects. Apart from these direct hydrogen projects, a great number of solar energy stations and wind farms (particularly common in California) can be seen as precursor of the hydrogen energy economy.

All hydrogen projects to date convert the universal but expensive energy carrier electricity with notable losses to hydrogen. Sometimes the cycle is completed and the hydrogen is converted back to electricity.

Direct production of hydrogen from solar radiation (e.g., by photochemical or biological methods) is still under research.

9.4.2. *Hydrogen Energy Economics*

Various factors can accelerate the introduction of the hydrogen technology, but do not exclude other solutions for the energy supply such as drastic savings or introduction of new energy forms. For time schedules for the introduction of hydrogen technology and other prognoses see [451], [454], [465]. The political decision to use hydrogen as an energy carrier reflects the following:

1. *Technological and Ecological Aspects.* The utilization of fossil and nuclear energy can be reduced in favor of energy savings, renewable resources, and solar energy. This could be forced by climate changes and environmental pollution.
2. *Economic Aspects.* Increased energy costs and storage costs for conventional primary energy and energy carriers could accelerate the introduction of the hydrogen economy.
3. *Political Aspects.* National hydrogen energy economics could be favored by the effect of primary energy import on the balance of trade, the creation of jobs by national energy programs, and the improvement of the structure of the economy.
4. *Security of Supply.* Energy produced from a local primary energy source can be stored in the form of hydrogen.
5. *Social Compatibility.* Energy production is coupled with an environmentally acceptable energy carrier.

Price estimates for hydrogen based on present-day technologies (see Fig. 119) [454, p. 341] depend on many factors. Comparisons of hydrogen production by means of solar cell plants, solar collector plants, parabolic mirror plants, or wind farms cannot consider the innovative potential of each technology over the projected time span.

Figure 119. Hydrogen production costs for four hydrogen plants and three different start-up dates (interest rate: 8 %, depreciation: 30 a, construction: 4 a, inflation: 5 %). Comparison with real escalating hydrogen (– – –) and natural gas (——) costs (J = annual real rate of escalation, cost of electricity production = E, of hydrogen production = H, of piping = P, of operation = O, and T of transport for 3300 km)

The plants are: PV = photovoltaic solar cell plants, ST = solar thermic, solar power plants, PM = parabolic mirror solar thermic plants, WE = wind energy farms [454]

Another method to assess the role of hydrogen technology in the future energy supply is to compare the efficiency of energy supply systems. In Figure 120 the efficiencies of room heating using electric power produced by photovoltaic means are compared in the Federal Republic of Germany. The power is generated inside the country and then distributed either in a hydrogen pipeline (A) or as such (B) to the user. The much more efficient power production in the Sahara is also considered. Energy can be transported directly as current (D) or as hydrogen (C).

Figure 120. Comparison of photovoltaic energy generation in the Federal Republic of Germany (A, B) and in arid regions in North Africa (Sahara) (C, D), transportation in the form of hydrogen (A, C) or in the electric grid (B, D). End use: room heating in the Federal Republic of Germany [466]

9.4.3. *International Research*

A particular advantage of hydrogen technology is that all necessary systems and components are in an advanced state of development. Some technologies, such as hydrogen transport and storage, have been used industrially for decades. In spite of this, intensive research is still required in important areas. These areas are being investigated by several countries which cooperate under the auspices of the International Energy Agency, IEA (Table 49) [467].

Table 49. Hydrogen research activities of some member countries of the International Energy Agency (IEA) [467]

Subtask	Subject	Federal Republic of Germany	Japan	Sweden	Switzerland	United States
Storage	Metal hydride storage	×	×	×	×	×
	Liquefaction of hydrogen	×				
	Hydrogen storage on carbon					×
Conversion	Engine with inert gas recirculation		×			
	LH_2-Pump for internal combustion engines	×				
	Reversible hydrogen storage electrode		×			
Safety	Alternation of material properties by hydrogen embrittlement	×	×			
	Safety aspects of hydrogen combustion	×				
	Man years 1986:	13	10.5	1.5	3.2	4.5
	Man years 1987:	11.8	10.5	1.5	4	4.5
	Man years 1988:	11	10.5	1.5	4	4.5

Canada. Canada plans to generate hydrogen by hydropower and to test applications in pilot projects. Some activities are listed in Table 49. Systems analysis studies regarding special applications for hydrogen have also been carried out [468]. Canadian activities involve basic research in universities, industry, (especially in the field of electrolysis), and national research centers (sponsored by the National Research Council, NRC).

Federal Republic of Germany [452], [466]. Industry, research institutions, and universities are continuing the development of hydrogen technology with the help of government funds. Pilot projects are described in Section Hydrogen Energy Economics. In the 1990s, work will concentrate on following areas:

1. Energy generation (photovoltaic and solar thermal techniques in cooperation with countries with high solar radiation intensities)
2. Hydrogen production (electrolysis, advanced alkaline electrolysis, high-temperature electrolysis, basic research on biological hydrogen generation)
3. Applications (fuel cells, stationary power applications, peak power, power – heat combined cycle)
4. Materials and safety

The Federal Republic of Germany takes the leading role in the international funding of hydrogen technology. State funding in the energy and renewable resources areas amounts to 200×10^6 DM/a; 100×10^6 DM of this sum are to be spent in the 1990s on hydrogen technology.

Japan. Japanese activities are concentrated in the Sunshine Project of the Ministry of International Trade and Industry (MITI). According to annual reports on this topic [469], the following areas are being investigated (1986):

1. Hydrogen production by SPE water electrolysis (see Section Electrolysis)
2. Storage and transportation of hydrogen by using metal hydrides
3. Utilization of hydrogen (combustion, reciprocating engines, cars, etc.)
4. Safety (explosion prevention).
5. Photochemical processes, thermochemical cycles (Br^- system cycle), high-temperature – high-pressure water electrolysis, and hydrogen from biomass

Funding has decreased continuously from a maximum of 950×10^6 Yen in 1980 to 190×10^6 Yen in 1987. However, funds for solar energy (which amounted to 7560×10^6 Yen in 1987) and overhead costs are not included in these figures. Japan is also a member of the IEA (see Table 49).

United States. Research in the United States deals principally with energy generation via solar radiation and thus only indirectly with hydrogen technology, although a remarkable amount of solar energy is generated, in the South and the West of the United States in particular. This energy is fed directly into the grid. Hydrogen is at present not under consideration as an energy carrier.

Basic research at various universities takes place within the IEA framework and is sponsored by industry and government.

Soviet Union. Proof of the high standard of research in hydrogen technologies was the 1988 report of the flight of a Tupolev aircraft powered by liquid hydrogen (see Section Hydrogen-Energy Conversion Systems).

This review deals with chemical and physical properties of hydrogen peroxide and gives detailed descriptions about the various production processes. Today, almost all hydrogen peroxide is produced by organic autoxidation processes, primarily the anthraquinone process. Other aspects in this review are handling, safety and usage of hydrogen peroxide. Hydrogen peroxide occurs naturally. Because of its chemical reactivity, hydrogen peroxide also has toxic properties. The formation and degradation of atmospheric hydrogen peroxide is photochemically mediated. Degradation of aquatic hydrogen peroxide is catalyzed by biological material or by transition metals. Toxicity data are collected for various organisms.

1. Introduction and Historical Aspects

The industrial production of hydrogen peroxide passed through three phases, starting with wet chemical processes, followed by electrochemical processes, and then by organic autoxidation processes. Almost all hydrogen peroxide is now produced by organic autoxidation (AO) processes, primarily the anthraquinone process.

Wet Chemical Processes. In 1818, L. J. Thenard [9] obtained hydrogen peroxide for the first time by treating barium peroxide [*1302-29-6*] with nitric acid. This process was improved by using hydrochloric acid to release hydrogen peroxide. The water-soluble barium chloride which

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a13_443.pub2

is formed simultaneously, was precipitated with sulfuric acid.

$$BaO_2 + 2\,HCl \rightarrow BaCl_2 + H_2O_2$$

$$BaCl_2 + H_2SO_4 \rightarrow BaSO_4 + 2\,HCl$$

$$BaO_2 + H_2SO_4 \rightarrow BaSO_4 + H_2O_2$$

With this reaction, THENARD established the foundation for the commercial manufacture of aqueous hydrogen peroxide solutions based on wet chemical processes, which began around 1880.

Industrial plants using the barium peroxide process were still operating until the middle of the 20th century. Around 1900, approximately 10 000 t/a of barium peroxide was processed by this technology, yielding ca. 2000 t/a of hydrogen peroxide. Sales opportunities for the coproduct barium sulfate ($BaSO_4$, blanc fixe) had a decisive effect on the profitability of the process.

The 3 % aqueous hydrogen peroxide solutions manufactured by the barium peroxide process had only a limited market because of their high production cost, low hydrogen peroxide content, and unsatisfactory stability due to impurities.

Electrochemical Processes. The introduction of electrochemical processes eliminated the disadvantages of the barium peroxide process.

In 1853, MEIDINGER discovered the formation of hydrogen peroxide during electrolysis of aqueous sulfuric acid [10]. In 1878, BERTHELOT showed that peroxodisulfuric acid [*13445-49-3*] is formed during this electrolysis and then hydrolyzed by water to give sulfuric acid and hydrogen peroxide via peroxomonosulfuric acid [*12188-01-1*] [11]:

$$2\,H_2SO_4 \rightarrow H_2S_2O_8 + H_2$$

$$H_2S_2O_8 + H_2O \rightarrow H_2SO_5 + H_2SO_4$$

$$H_2SO_5 + H_2O \rightarrow H_2SO_4 + H_2O_2$$

$$2\,H_2O \rightarrow H_2O_2 + H_2$$

In 1905, following the work of ELBS and SCHOENHERR [12], G. TEICHNER developed an electrolytic process at the Konsortium für Elektrochemische Industrie. The first hydrogen peroxide plant based on this new technology went on stream in 1908 at the Österreichische Chemische Werke in Weissenstein. The *Weissenstein process* was followed in 1910 by the *Münchner process* developed by A. PIETZSCH and G. ADOLPH at the Elektrochemische Werke, Munich, and then in 1924 by the *Riedel–Loewenstein process* developed by L. LOEWENSTEIN and first used by Riedel-de-Haen. In these processes, an ammonium sulfate solution was electrolyzed instead of free sulfuric acid, and the resulting ammonium peroxodisulfate (Riedel–Loewenstein) or potassium peroxodisulfate derived therefrom (Pietzsch–Adolph) was hydrolyzed. After introduction of these processes, production (calculated as 100 % hydrogen peroxide) increased steadily and, in 1950, reached approximately $(30–35) \times 10^3$ t/a [13].

Organic Autoxidation Processes. The decisive breakthrough in industrial production of hydrogen peroxide, which enabled the construction of modern large-scale plants, came with the development of organic autoxidation processes, especially the anthraquinone process.

In 1901, MANCHOT discovered that hydroquinones (or hydrazobenzenes) react quantitatively with oxygen to form quinones (or azobenzenes) and hydrogen peroxide [14]. In 1932, WALTON and FILSON in the United States went back to this work and proposed a cyclic process for the manufacture of hydrogen peroxide based on azobenzene–hydrazobenzene [15].

PFLEIDERER of I. G. Farbenindustrie AG, Ludwigshafen (BASF), subsequently developed a process for the alkaline autoxidation of hydrazobenzene in which sodium peroxide is obtained instead of free hydrogen peroxide [16]. This process was used on an industrial scale by Kymmene AB in Kuusankoski (Finland) under BASF licence (see Section 4.4.4.

The azobenzene process had two major technical drawbacks: hydrogenation of azobenzene was performed with sodium amalgam, and oxidation of hydrazobenzene proceeded satisfactorily only in alkaline solution. PFLEIDERER and RIEDEL overcame these problems by using alkylated anthraquinones instead of azobenzene. Between 1935 and 1945, BASF developed the Riedel–Pfleiderer process (generally referred to as the anthraquinone or AO process) in a pilot plant with a monthly output of 30 t. At the

end of World War II, this work was stopped in Germany because of Allied Control Commission Regulations, but it formed the basis for all present production processes. In 1953, Du Pont of Memphis, Tennessee, commissioned the first hydrogen peroxide production plant based on the AO process. Several other companies began to produce hydrogen peroxide by this process, and production capacity increased greatly. In 2002, the global production capacity excluding China was estimated to be 2.8×10^6 t/a (calculated as 100 % H_2O_2) [17].

Another organic autoxidation process, the 2-propanol process, used by Shell in Norco (United States) between 1957 and 1980, made only a limited contribution to the increase of hydrogen peroxide production with an annual production capacity of about 15 000 t.

Various patents on direct combination of hydrogen and oxygen have been published but up to now, the direct synthesis of hydrogen peroxide has not been implemented on a large industrial scale.

2. Physical Properties

Hydrogen peroxide [*7722-84-1*], M_r 34.016, is a clear, colorless liquid which is miscible with water in all proportions. Hydrogen peroxide and highly concentrated aqueous solutions (> 65 wt %) are soluble in a variety of organic solvents such as carboxylic esters.

Hydrogen peroxide and water do not form an azeotropic mixture and, in theory, can be separated completely by distillation. In practice, 100 wt % hydrogen peroxide is obtained by fractional crystallization of highly concentrated (ca. 90 wt %) aqueous solutions. Pure 100 wt % hydrogen peroxide is stable at room temperature. It is of scientific interest only and is not produced on an industrial scale.

Data pertaining to molecular structure (obtained by neutron diffraction on solid H_2O_2) are as follows [18]:

Bond length, O—O	145.3 ± 0.7 pm
Bond length, O—H	99.8 ± 0.5 pm
Bond angle, O–O–H	102.7 ± 0.3°
Azimuthal angle	90.2 ± 0.6°

Figure 1. Vapor pressure of aqueous hydrogen peroxide solutions

Figure 2. Partial pressure of hydrogen peroxide over aqueous hydrogen peroxide solutions

Physical constants of hydrogen peroxide and water are compared in Table 1. For a more detailed comparison, see [20]. Physical constants of some aqueous hydrogen peroxide solutions in commercially available concentrations are listed in Table 2.

The vapor pressure and partial pressure of aqueous hydrogen peroxide solutions are shown as a function of temperature in Figures 1 and 2, respectively. Figure 3 shows the vapor–liquid equilibrium curve for aqueous hydrogen peroxide solutions [21].

Figure 3. Vapor–liquid equilibrium curve for water–hydrogen peroxide

Figure 4. Freezing point curve for water–hydrogen peroxide

The solid–liquid phase diagram (Fig. 4) shows eutectic points for the mixtures

ice–$H_2O_2 \cdot 2\ H_2O$ at 45.2 wt % hydrogen peroxide and for solid H_2O_2–$H_2O_2 \cdot 2\ H_2O$ at 61.2 wt % hydrogen peroxide with a congruent melting point for the compound $H_2O_2 \cdot 2\ H_2O$ between them.

Heat of formation and of decomposition of hydrogen peroxide are:

$H_2(g) + O_2(g) \Rightarrow H_2O_2(g)$	−136.2 kJ/mol
$H_2(g) + O_2(g) \Rightarrow H_2O_2(l)$	−187.9 kJ/mol
$H_2O_2(g) \Rightarrow H_2O\ (g) + 1/2\ O_2(g)$	−105.8 kJ/mol
$H_2O_2(l) \Rightarrow H_2O\ (l) + 1/2\ O_2(g)$	−98.3 kJ/mol

3. Chemical Properties

Dissociation. Hydrogen peroxide is weakly acidic in aqueous solution, with a dissociation constant of 1.78×10^{-12} (pK 11.75) at 20 °C. As a weak acid, hydrogen peroxide forms salts with various metals.

Oxidation and Reduction. Hydrogen peroxide can behave both as an oxidizing and as a reducing agent (Tables 3 and 4). Systems with a redox potential $E_0 < -1.80$ V at pH 0 cannot be oxidized by hydrogen peroxide; systems with a redox potential $E_0 > -0.66$ V at this pH cannot be reduced by hydrogen peroxide [6, 22].

Table 3. Hydrogen peroxide as an oxidizing agent [20]

Redox reaction	Standard potential E_0, V *
pH 0	
$HOOH + 2\ H^+ + 2\ e^- \Rightarrow 2\ HOH$	+1.80
$HSO_3^- + HOH \rightarrow SO_4^{2-} + 3\ H^+ + 2\ e^-$	−0.17
$NO_2^- + HOH \rightarrow NO_3^- + 2\ H^+ + 2\ e^-$	−0.94

$2\ e^- + ClO^- + HOH \Rightarrow Cl^- + 2\ OH^-$	+ 0.89

* Standard potential of redox reactions measured against a hydrogen electrode (25 °C, 100 kPa).

Decomposition of hydrogen peroxide occurs with disproportionation

$$H_2O_2 \rightarrow H_2O + 1/2\ O_2$$

and is extremely important in handling hydrogen peroxide during storage and in the laboratory. This reaction is highly exothermic (see Chapter 2) and takes place in the presence of small amounts of catalyst even in aqueous solution. In the absence of catalyst, it occurs only in the gas phase at high temperature.

Decomposition can be catalyzed both homogeneously by dissolved ions (especially of the metals iron, copper, manganese, and chromium) and heterogeneously by suspended oxides and hydroxides (e.g., those of manganese, iron, copper, palladium, or mercury) and by metals such as platinum, osmium, and silver.

Substitution. The hydrogen atoms of hydrogen peroxide can be substituted by alkyl and acyl groups, leading to the formation of

H−O−O−R	alkyl hydroperoxides
R−O−O−R	dialkyl peroxides
H−O−O−Ac	percarboxylic acids
Ac−O−O−Ac	diacyl peroxides

Hydrogen peroxide forms peroxohydrates with a number of compounds. Addition compounds with sodium carbonate (sodium carbonate peroxohydrate [*15630-89-4*]) and with urea (urea peroxohydrate [*124-43-6*]) are industrially important. For a detailed description of peroxo compounds see → Peroxo Compounds, Inorganic; → Peroxy Compounds, Organic.

4. Production

4.1. Anthraquinone Process (AO Process)

4.1.1. Principles

In the AO process, 2-alkyl-9,10-anthraquinones react with hydrogen in the presence of a catalyst to form the corresponding hydroquinones.

R = alkyl

After the catalyst is removed (otherwise, the hydrogen peroxide would decompose), the hydroquinones are oxidized to quinones with oxygen (usually air) with simultaneous quantitative formation of hydrogen peroxide:

Hydrogen peroxide is extracted with water, and the quinones are returned to the hydrogenator to complete the loop.

The AO process, therefore, leads to the net formation of hydrogen peroxide from gaseous hydrogen and oxygen.

Solvents. Anthraquinones must be dissolved in a suitable solvent for hydrogenation, oxidation, and extraction (the so-called working solution). Although a number of individual solvents have been proposed (e.g., aromatic alcohols or their esters [24]), solvent mixtures are almost always used because the quinones and hydroquinones have different solubilities. Quinones dissolve readily in nonpolar, aromatic solvents (quinone solvents). Hydroquinones dissolve well in polar solvents, especially alcohols and esters (hydroquinone solvents). Proposed solvents or solvent mixtures are

Quinone solvents
- Benzene, xylene [25, 28]
- tert-Butylbenzene [26]
- Trimethylbenzene [28]
- Tetramethylbenzene (isodurene)[29]
- Mixtures of polyalkylated benzenes, e.g., C9-C11 aromatic solvents [30, 31]
- Methylnaphthalene [32]

Hydroquinone solvents
- Alkyl phosphates, e.g., tris-(2-ethylhexyl)-phosphate [33]
- Nonyl alcohols, e.g., diisobutylcarbinol [32]
- Alkylcyclohexanol esters, e.g., 2-methyl-cyclohexylacetate [34]
- *N*,*N*-Dialkyl carbonamides, e.g., *N*,*N*-dibutyl propionamide [35]
- *N*-Alkyl *N*-aryl carbonamides e.g. *N*-ethyl-*N*-phenyl benzamid [36]
- *N*,*N*-Dialkyl carbamates, e.g., 2-ethylhexyl-*N*-butylcarbamate [37]
- Tetraalkyl ureas, e.g., tetra-*n*-butylurea [42]
- Cycloalkyl ureas, e.g., dihexyl propyleneurea [38]
- Phenylalkyl ureas, e.g., *N*,*N*-dibutyl-*N*′-methyl-*N*′-phenylurea [39]
- *N*-Alkyl-2-pyrrolidones, e.g., octyl pyrrolidone [40]
- *N*-Alkyl caprolactams, e.g., *n*-octyl caprolactam [41]

Solvent mixtures [43, 44]:
- Polyalkylated benzenes and alkyl phosphates [30]
- Polyalkylated benzenes and tetraalkyl ureas [42]
- Trimethylbenzenes and alkylcyclohexanol esters [28]
- Methylnaphthalene and nonyl alcohols [32]

The following criteria must be fulfilled when choosing solvents and preparing solvent mixtures:

1) Good solubility of both quinone and hydroquinone
2) Good stability in the hydrogenator and oxidizer
3) Low solubility in water and aqueous hydrogen peroxide solutions
4) Sufficiently lower density than water to ensure separation of the two phases during extraction
5) Low volatility, i.e., high boiling point and flash point
6) High distribution coefficient for hydrogen peroxide in the solvent–water system
7) Low toxicity

Quinones. Criteria similar to those used for selecting solvents also apply to the quinone or quinone mixture which is used as the working compound:

1) Good solubility of the quinone form
2) Good solubility of the hydroquinone form
3) Good resistance to oxidation
4) Good availability

The choice of quinone depends mainly on the properties, especially the solubility, of the products formed in the AO process. Examples of working compounds are 2-ethylanthraquinone [*84-51-5*] [45], 2-tert-butylanthraquinone [*84-47-9*] [46], 2-neopentylanthraquinone [*123257-96-6*] [47], 2-isohexenylanthraquinone [*71308-16-2*] [48], diethylanthraquinones [49], mixtures of 2-amylanthraquinones [54], and mixtures of different alkylanthraquinones [50–53].

The formation of degradation products and their ability to be regenerated to active quinones also play a role in the decision. In addition to hydroquinone formation, a number of secondary reactions occur during the hydrogenation step; of these, hydrogenation of the anthraquinone ring system is particularly important. One ring of the anthraquinone molecule, preferably the one that is not substituted by an alkyl group, is hydrogenated. In the case of R=ethyl, this is accomplished with selectivities higher than 90 %.

2-Alkyl-5,6,7,8-tetrahydro-9,10-dihydroxyanthracene is formed, which is also oxidized by oxygen to regenerate the 2-alkyl-5,6,7,8-tetrahydroanthraquinone (known as "tetra"), with simultaneous quantitative formation of hydrogen peroxide.

Although "tetra" is more readily hydrogenated than a 2-alkylanthraquinone, the resulting "tetra" hydroquinone is much more difficult to oxidize than the readily oxidizable anthrahydroquinone. The kinetics and basic physicochemical parameters of tetrahydroquinone oxidation have been studied [55–57]. Small amounts of amines accelerate hydroquinone oxidation [58].

The formation of "tetra" in the synthesis loop depends on process conditions and has led to two methods for carrying out this process: the "anthra" system and the "all-tetra" system.

Anthra System. The slower oxidation rate of the "tetra" hydroquinone causes difficulties in the oxidizer. Actions have therefore been proposed which suppress the formation of "tetra" or dehydrogenate it to anthraquinone.

When the "tetra" content of the working solution is kept low (i.e., if 2-alkylanthrahydroquinone is formed almost exclusively during hydrogenation), the process is referred to as the "anthra" system.

"Tetra" formation is suppressed by using selective catalysts [59], special solvents [60], special working compounds [61], and mild hydrogenation conditions [62] (e.g., the use of olefins has been recommend for the steady dehydrogenation of "tetra" [63]).

"Tetra" can be dehydrogenated in the presence of activated aluminum oxide:

When the "anthra" system is used, tautomeric 2-alkyl-10-hydroxy-9-anthrone (oxanthrone) is also formed during hydrogenation [13, 64]:

Oxanthrone

Oxanthrone is not oxidized by oxygen to form hydrogen peroxide and therefore leads to loss of active quinone. Further hydrogenation of oxanthrone leads to anthrone and tetrahydroanthrones [65]. Although oxanthrone and anthrone can be regenerated to active quinones, subsequent oxidative dimerization of anthrone may lead to dianthrones which represent a loss of quinone [13].

The buildup of anthrones and oxanthrones can be minimized by adding an aromatic tertiary amine to the working solution [66] or by pretreatment of the hydrogenation catalyst with halides [67].

"All-Tetra" System. If "tetra" formation is not suppressed during hydrogenation or "tetra" is not dehydrogenated, an equilibrium is reached in which the hydroquinone charged to the oxidizer consists exclusively of 2-alkyl-5,6,7,8-tetrahydroanthrahydroquinone. Such a system is called an "all-tetra" system.

If anthraquinone is hydrogenated in addition to "tetra" during the hydrogenation step, hydrogen transfer occurs [68]:

This means that the hydroquinone leaving the hydrogenation step is always the "tetra" hydroquinone. Dianthrone formation does not occur in the "all-tetra" system, but oxidation of "tetra" hydroquinone leads to a byproduct, the so-called epoxide:

The epoxide does not participate in the formation of hydrogen peroxide and leads to a loss of active quinone. The formation of epoxides seems to be minimized when using high oxygen content [69], or mixing hydrogenated working solution with a portion of oxidized working solution containing hydrogen peroxide and then feeding to the oxidizer [70]. Different measures have been suggested for regenerating "tetra" from the epoxide [71, 73] (see Chapter 4.1.2.4)

If the "tetra" content of the "all-tetra" system is high, another byproduct can be formed, namely, 2-alkyl-1,2,3,4,5,6,7,8-octahydroanthraquinone [13]:

Although this "octa" hydroquinone is oxidized by oxygen to quinone with the formation of hydrogen peroxide, the reaction is too slow to be important in the formation of hydrogen peroxide. "Octa" thus represents a decomposition product from which quinone cannot be regenerated.

Octa formation depends on hydrogenation conditions and catalyst type. Other degradation products may be formed besides octa [65, 74, 75].

4.1.2. Process Description

The cyclic Riedel–Pfleiderer or BASF process (Chap. 1) forms the technological basis for all modern AO processes. Developments include improvement of the individual process steps, use of stable working solutions, and use of selective hydrogenation catalysts. The basic principles of the process are illustrated in Figure 5.

Hydrogenation. From the storage tank or hydrogenation feed tank (a), the working solution enters the hydrogenator (b) where it is hydrogenated in the presence of a suspended, supported, or fixed-bed catalyst.

If a suspended catalyst (e.g., palladium black or Raney nickel) or a supported catalyst (e.g., palladium) is used, the hydrogenation step includes a main filtration stage which retains the catalyst and allows it to be returned to the hydrogenator. The heat of reaction released during hydrogenation can be removed (1) before hydrogenation (by cooling the oxidized working solu-

tion), (2) during hydrogenation (by cooling the reactor), or (3) after hydrogenation (by cooling the hydrogenated working solution).

Oxidation. Before the hydrogenated working solution that contains hydroquinone can be fed to the oxidation step, it must pass through a safety filtration stage (c). This is particularly important because the hydrogenation catalysts used in the AO process (palladium and Raney nickel) also catalyze the decomposition of hydrogen peroxide. Even a small amount of these catalysts in the oxidation and extraction steps would lead to considerable loss of hydrogen peroxide and serious disturbances.

During the oxidation step (d), the hydrogenated working solution is gassed with air. Dissolved hydroquinones are oxidized to quinones, and hydrogen peroxide is formed.

After the working solution has been separated (e_1), air from the oxidation step passes over activated carbon adsorbers (f), and adsorbed solvent is recovered from them. Several adsorbers are usually loaded and regenerated alternately, for example, with steam.

Extraction and Recovery of the Working Solution. The oxidized working solution is then treated with water to extract hydrogen peroxide (g).

The working solution leaving the extraction unit must be adjusted to a specific water content before being returned to the hydrogenation step. Free water taken up by the working solution during extraction is separated (e_2) and the water content is adjusted to the desired level in the drier (h).

To purify the working solution and regenerate the quinone decomposition products into active quinones, some or all of the working solution is passed through a regeneration step (n).

Hydrogen Peroxide Concentration. Crude aqueous hydrogen peroxide from the extraction stage (H_2O_2 concentration 15–40 wt %) is fed into the crude product storage tank (j) via a prepurification unit (i).

From the crude product storage tank, aqueous hydrogen peroxide goes to the concentration unit (k) where it is distilled. Here, hydrogen peroxide is freed from most of its impurities and concentrated to the commercial concentration of 50–70 wt %; it is then collected in a storage tank (l).

Water vapor produced during distillation is condensed and fed into the water storage tank (m).

Auxiliary Processes. A number of additional processes are required to maintain the AO operation. For example, to maintain hydrogenation activity, part of the catalyst is removed, regenerated in the catalyst regeneration area (q), and returned to the hydrogenator. To compensate for quinone and solvent losses, working solution is periodically made up with anthraquinone and solvent (o, p).

4.1.2.1. Hydrogenation

The hydrogenation step is the most important step of modern AO processes. Quinone decomposition products that cannot be regenerated into active quinone are formed during this step (cf. Section 4.1.1). New hydrogenation catalysts and hydrogenation reactors have been developed that deviate totally from the BASF principle. Here, design of the hydrogenator depends largely on the type of catalyst used.

Four typical reactors for the three usual catalyst systems (suspended, supported, and fixed-bed catalysts) are discussed in this section.

BASF Hydrogenation Step. The hydrogenation step in the BASF plant (Fig. 6) uses a Raney nickel catalyst at a slight excess pressure of approximately 0.2 MPa and at 30–36 °C. Because Raney nickel is sensitive to oxygen, the working solution from the extraction or drying and purification steps cannot be fed directly into the hydrogenator. This working solution still contains residual hydrogen peroxide and must be passed over a decomposition catalyst (e.g., supported Ni–Ag), together with a fraction of the hydrogenated working solution (which also contains hydroquinone), to remove hydrogen peroxide completely:

Figure 6. BASF hydrogenation step
a) Precontact column; b) Hydrogenator feed tank; c) Stirred tank reactor with internal filters; d) Catalyst feed tank; e) Safety filtration; f) Catalyst separator; g) Pump; h) Oxidizer feed tank

The solutions are passed through the precontact column (Fig. 6, a) and collected in the hydrogenator feed tank (b). The working solution is then pumped into the stirred vessel reactor (c) and is gassed with hydrogen in the presence of Raney nickel. Periodic addition of small amounts of hydrogenation catalyst from the catalyst feed tank (d) allows a constant rate of hydrogen conversion in the hydrogenator. Hydrogenated working solution is collected in the oxidizer feed tank (h) through the internal filters in the stirred vessel, thus exploiting the excess pressure in the reactor. The solution is then led into the oxidation step via the safety filter (e). A sidestream of hydrogenated working solution is withdrawn and recycled to the precontact column (a).

When the concentration of Raney nickel in the hydrogenation reactor reaches a certain limit, the content of the reactor is drained into the catalyst separator (f). Raney nickel settles to the bottom, and catalyst-free supernatant is pumped back to the hydrogenator.

A significant disadvantage of Raney nickel as catalyst is its limited selectivity, i.e., the ratio of hydroquinone formation to "tetra" formation. BASF largely eliminated this by pretreating the catalyst with ammonium formate [76].

Alternatives were subsequently suggested for pretreating Raney nickel (e.g., nitriles [77], amines [78], and aldehyde solutions [79]). In recent years, more selective nickel catalysts, based on Ni-B or Ni-Cr-B alloys were developed [80].

The pyrophoric properties of Raney nickel also require more stringent safety procedures when handling the material. Raney nickel is still used today in some AO plants, but palladium catalysts are preferred because of their higher selectivity and simpler handling.

Degussa Hydrogenation Step. Degussa proposed the use of palladium black as the hydrogenation catalyst. This exploits the advantages offered by a suspended catalyst and avoids the disadvantages of Raney nickel. Equipment that allows good conversion of hydrogen with very finely distributed palladium black is shown in Figure 7 [81].

The most important feature of the loop reactor (c) is the connection in series of pipes with different diameters. The working solution flows downward in the large pipes at a rate of 0.7–1.5 m/s and flows upward in the narrower pipes at 1.5–3 m/s. Efficiency can be improved by installation of internal plate-stacks with a channel width of 10-50 mm [82] or external premixing of gas and liquid [83].

Degussa proposed a carbon filter [84]. Ceramic [85] and cross-flow [86] filters can also be used. A decline in filter performance can be overcome by periodic back flush with hydrogenated working solution through the filter into the hydrogenator.

Figure 7. Degussa hydrogenation step
a) Reactor circulating pump; b) Filter; c) Loop reactor; d) Separator; e) Oxidizer feed tank; f) Back flush pump

Advantages of this hydrogenation system are

1) Almost complete conversion of hydrogen
2) Nonpyrophoric catalyst
3) Easy exchange of palladium black
4) Easy regeneration of the catalyst

Laporte Hydrogenation Step. Laporte Chemicals and other companies proposed the use of supported palladium catalysts [87]. Supports based on alumina [88], silica [89], and sodium aluminum silicate [90] are used. These catalysts have the advantage that their particle diameter in the range of 0.02–0.2 mm makes their filtration and recirculation to the reactor simpler than those of palladium black.

Laporte proposed the apparatus shown in Figure 8 for industrial hydrogenation [91]. The reactor contains a series of tubes whose lower ends lie just above the bottom of the reactor and whose top ends are just below the liquid surface. Hydrogen is fed into the bottom of each tube, and very small gas bubbles are formed by distributors. Upward flow occurs in the tube due to the density difference between the solutions in the tube and in the reactor. The catalyst suspension is drawn into the pipe by the continuous flow of working solution. To obtain a sufficiently high airlift effect in the tube, hydrogen must be circulated continuously. Continuously stirred tank reactors (CSTR) [92] and bubble-column reactors are also in use.

Figure 8. Laporte hydrogenation step
a) Hydrogenator; b) Reactor tubes; c) H_2 compressor; d) Internal filter

Fixed-Bed Hydrogenation Step. Fixed-bed hydrogenation represents a simple solution for the hydrogenation step; it involves a palladium catalyst and avoids the problem of filtration and recirculation of catalyst into the reactor. The first industrial fixed-bed hydrogenation unit for the AO process was commissioned by FMC (Fig. 9) [94].

Figure 9. FMC hydrogenation step
a) Fixed-bed reactor; b) Catalyst; c) Reactor circulating pump; d) Heat exchanger; e) Hydrogenator feed pump

Most fixed-bed catalysts have a diameter of 0.2–5 mm and a palladium load of 0.1–0.5 %. The working solution is pumped to the top of the reactor. A side stream of the hydrogenated working solution is also fed into the fresh working solution after the heat of reaction has been removed in a heat exchanger (d). The catalyst must fulfill a number of requirements such as

1) High abrasion resistance to allow simplification of the filtration step
2) A long working life because replacing a fixed-bed catalyst is more complicated than replacing a suspended catalyst
3) Good productivity
4) Easy regeneration of the catalyst

External [98] or internal [99] static mixers may be used to ensure good liquid/gas dispersion. To enhance performance, operation in the foam regime with a liquid/gas ratio not higher than 1.5/10, temperatures of 45–75 °C, and a pressure of 0.18–0.5 MPa [93] is proposed.

A fixed-bed reactor with honeycomb monoliths is described by EKA [95]. The monoliths contain parallel channels with a diameter of 1–3 mm. Applied to the walls is a thin layer of porous silica gel, coated with palladium.

Desactivation plays an important role when operating fixed-bed catalysts. Impact of factors like type of support [96] or water [97] on side reactions was studied. Several measures, e.g., treatment with steam and hydrogen peroxide [100] or acid wash [101] are described for catalyst regeneration.

Figure 10. BASF oxidation step

In recent years, especially AO plants built in China were equipped with fixed-bed hydrogenation.

4.1.2.2. Oxidation

In industrial plants, the catalyst-free hydrogenated working solution is usually oxidized with slightly pressurized air (up to 0.5 MPa). The oxidizer off-gas is then directed to a series of activated carbon adsorbers to purify it and recover the solvents escaping with it.

For economic reasons, the following objectives are sought in designing industrial oxidation reactors:

1) Efficient utilization of atmospheric oxygen to reduce the volume of the off-gas and the size of activated carbon adsorbers
2) Low compressor pressure to decrease energy costs
3) Small reactor volume or reduced holdup of working solution to lower investment costs for equipment and working solution

BASF Oxidation Step (Fig. 10). A working solution containing benzene as the quinone solvent has been used at BASF. For safety reasons and to minimize the volume of off-gas, the BASF oxidation step uses a nitrogen–oxygen mixture. The mixture is cycled in a closed circuit, and its composition is kept constant by adding pure oxygen to compensate for the amount consumed in the formation of hydrogen peroxide.

Hydrogenated working solution enters a separator (a) and then flows through four oxidation columns (b) arranged in series as a cascade. Oxidized working solution flows into the extractor feed tank (d) via a siphon (c). The nitrogen–oxygen mixture is compressed and fed into each of the four reactors.

Off-gas from the reactors is collected in a pipe and separated from entrained droplets of working solution. After compensation for consumed oxygen, the gas mixture is returned to the compressor (e).

Degussa Oxidation Step (Fig. 11) [102]. The hydrogenated working solution flows cocurrently upward with the oxidizing air through the first reactor. The working solution and air are separated in the upper part of the reactor. Off-gas from the reactor is fed to the activated carbon adsorption unit, and working solution flows into the second and third reactors, which are installed in series. The air needed for oxidation is pressurized with a compressor (c) and fed to the third reactor. The working solution and air flow

countercurrently, but both streams are divided into cocurrent flow segments.

Laporte Oxidation Step (Fig. 12). In Laporte's Warrington plant, oxidation was carried out in a packed cocurrent flow column [103, 104]. The entire volume of the oxidation reactor (a) was used for air gassing. The air and the working solution leaving the top of the column were fed together into a separator (b). The air then reached the alternately operated two-stage activated carbon adsorbers (c), and the working solution passed to the extraction stage. To enhance gas-liquid mass transfer, premixing of working solution and air by a venturi tube is proposed [105]. The use of a tubular reactor with static mixing elements is described by Kemira in [106].

Figure 12. Laporte oxidation step
a) Oxidation reactor; b) Separator; c) Activated carbon adsorber; d) Air compressor

Allied Chemical Oxidation Step. To shorten the residence time of the working solution in the oxidation step, Allied Chemical suggested a counterflow reactor in which residence times are less than 2.5 min at a partial oxygen pressure of 70–90 kPa [107]. Space–time yield can be improved by using perforated trays with small hole size (cross-sectional area of holes below 3 mm^2) [108].

4.1.2.3. Extraction and Drying

In the BASF plant, a sieve-tray extraction column extracts hydrogen peroxide from the working solution. A number of other extractors, such as packed columns, pulsed packed columns, and Podbielniak extractors, have been proposed.

Besides extraction column design, the extraction efficiency is strongly influenced by the distribution coefficient, which is depending on working solution composition (e.g., type of hydroquinone solvent).

It has been found, that by injection of a small amount of air into the extraction column (gas-agitated sieve plate column) extraction efficiency is increased by 30–40 % [109]. Processes which integrate oxidation and extraction in a single apparatus are also known [112, 113].

Working solution leaving the extraction unit contains dispersed water droplets and is led into coagulators and separators to separate free water. The working solution is then dried to a specific water content.

Because the solubility of water in the working solution depends on temperature, its moisture content can be adjusted by carrying out the extraction at low temperature, separating the dispersed water, and then increasing the temperature of the working solution by about 30 °C before it reaches the hydrogenation step [110]. The working solution may be alternatively dried by using the off-gas from the oxidation step [111].

In extraction and drying according to BASF (Fig. 13), working solution leaving the head of the extraction column (a) is initially freed from entrained water in a water separator (b). The working solution then passes through aqueous potassium carbonate solution for drying (c).

4.1.2.4. Working Solution Purification and Regeneration

During the constant circulation of working solution, degradation products are formed not only from the working compound, but also from the solvents. These degradation products must be removed from the working solution to prevent (1) deterioration of the crude hydrogen peroxide (color, smell, dissolved organic compounds), (2)

Figure 13. BASF extraction and drying step
a) Sieve–tray extraction column; b) Water separator; c) Drier; d) Potassium carbonate solution separator; e) Potassium carbonate solution make-up and feed tank; f) Potassium carbonate concentration

an increase in density and viscosity of the working solution, and (3) a decrease in interfacial tension of the working solution, which promotes the formation of an emulsion during extraction. In addition, degradation products decrease the activity and lifetime of the hydrogenation catalysts. Regeneration and purification can be performed with hydrogenated working solution or with working solution after extraction.

Numerous methods have been suggested for purifying the working solution and regenerating active quinone from the quinone degradation products. Examples include the following:

1) Treatment of the hydrogenated working solution with alkaline substances [71] or aqueous alkali hydroxide [72]
2) Treatment of the working solution with sodium aluminum silicates at 50–200 °C [114]
3) Treatment of the working solution after hydrogenation or extraction with active aluminum oxide at 20–150 °C [115–118]
4) Treatment with alkali hydroxide, calcium hydroxide, ammonia, or amines in the presence of oxygen or hydrogen peroxide [119]
5) Treatment of the working solution with aqueous sodium hydroxide or potassium hydroxide solution (8–17 mol/L) in the presence of oxidants [120]
6) Treatment with solvent and liquid carbon dioxide [121]
7) Treatment with a noncyclic hydrocarbon [122]

4.1.2.5. Purification of Crude Hydrogen Peroxide

The aqueous hydrogen peroxide leaving the extraction is impure. Separators are usually installed after extraction (Section 4.1.2.3) [123]. Measures for reducing the amount of dissolved organic compounds include treatment of the crude product with polyethylene [124], ion exchangers [125, 126], or hydrocarbons [127, 128]. Water-soluble organic compounds can also be oxidized by heating and then extracted with suitable solvents (e.g., the quinone solvent) [129]. The effect of purification on carbon content of crude hydrogen peroxide is illustrated in Table 5.

Table 5. Processes for purifying crude hydrogen peroxide

Process	Carbon content of H_2O_2, mg/L		Reference
	Before purification	After purification	
Extraction with xylene	580	450	[130]
Extraction with methylcyclohexanol acetate	580	390	[130]
Extraction with xylene and methylcyclohexanol acetate	580	370	[130]
Brief treatment with 0.5 wt % activated carbon	134	11	[131]
Treatment with adsorber resin	320	140	[132]
	1000	100	[133]
Reverse-osmosis membrane	130	18	[134]
Supercritical carbon dioxide	145	84	[135]

Purified crude product is then usually fed to a distillation unit where it is purified further and concentrated to the usual commercial concentration of 50–70 wt % hydrogen peroxide. This product can be used directly in a number of applications. Reverse osmosis membranes can also be used to purify crude, distilled or concentrated (up to 70 %) hydrogen peroxide [134, 137]. A disadvantage of this procedure is that only part of the feedstream leaves the unit as purified permeate, while the impurities are accumulated in the retentate.

For use in the electronics industry, hydrogen peroxide with a very low content (ppt level) of metal impurities is needed. Many patents deal with further purification of crude or prepurified hydrogen peroxide with a combination of cation- and anion- exchange resins [136–140]. Some methods make use of of reverse osmosis in combination with other methods [134, 141, 142], adsorption of metal impurities on activated carbon [143], stannic oxide [144], or zirconium phosphate [145].

4.1.2.6. Concentration of Hydrogen Peroxide

Water and hydrogen peroxide do not form an azeotrope; their boiling point difference at atmospheric pressure is 50.2 °C (Table 1). Distillation of water from aqueous hydrogen peroxide can therefore be used to concentrate the solution or to completely separate hydrogen peroxide from water. A number of technical safety requirements must be observed. Distillation of dilute solutions has been used industrially to produce commercial 50–70 wt % hydrogen peroxide solution; the technology is described in [3, 5, 146–152]. The use of structered packings [150] in distillation columns enhances perfomance. Concentrations higher than 90 % are preferably produced by crystallization [153, 154].

4.2. 2-Propanol Process (Shell Process)

In 1945 Harris discovered that primary and secondary alcohols react with oxygen to form hydrogen peroxide and an aldehyde or ketone, respectively [155]:

$$RCH_2OH + O_2 \rightarrow RCO + H_2O_2$$

$$R_2CHOH + O_2 \rightarrow R_2C{=}O + H_2O_2$$

Oxidation of the alcohol can be carried out in the liquid or the gas phase. Because aldehydes formed in the reaction with primary alcohols are oxidized easily, only the oxidation of secondary alcohols, especially 2-propanol [*67-63-0*], has industrial importance.

A process for the simultaneous production of hydrogen peroxide and acetone [*67-64-1*] by atmospheric oxidation of 2-propanol was first suggested by Rust [156, 157].

Reaction of 2-propanol with oxygen in the liquid phase does not require a special catalyst because it is catalyzed by the hydrogen peroxide product. However, a small amount (0.5–1 wt %) of hydrogen peroxide is added to 2-propanol to shorten the induction period. The reaction proceeds as follows:

$$HOOH \rightarrow 2\,HO^{\bullet}$$

Secondary reactions also take place but are not discussed here. To reduce the formation of byproducts, particularly acetic acid, which affects the quality of hydrogen peroxide, only part of the 2-propanol is oxidized, and oxidation is carried out in several consecutive steps at decreasing temperature [158].

The 2-propanol process is used only in two plants in the former Soviet Union, which have been operating since 1968 and 1972. The Shell Oil Company decommissioned its plant in Norco, Louisiana in 1980 [159, 160]; that plant had been in operation since 1957. The technology of the Shell 2-propanol process is described in [161]. The hydrogen peroxide yield of the Russian plants based on 2-propanol or atmospheric oxygen is 87–98 %; the acetone yield is 92–94 % [162, 163].

An alternative process, which makes use of the liquid phase oxidation of methylbenzyl alcohol, coproduct in the production of propylene oxide by epoxidation of propylene with ethylbenzene hydroperoxide, was developed by Arco but has not been commercialized [164–166]. Similar to the AO process the operations include hydrogenation, oxidation, extraction, and purification steps. Oxidation of methylbenzyl alcohol with air at elevated temperature yields hydrogen peroxide and acetophenone. Methylbenzyl alcohol conversion in the reactor is 30 % with H_2O_2 selectivity about 80 %. The hydrogen peroxide content in the organic phase at the exit of the oxidizer is approximately 5 wt %. After addition of ethylbenzene hydrogen peroxide is extracted with water. The organic phase overflowing at the top of the extractor contains methylbenzyl alcohol, ethylbenzene and acetophenone. Whereas ethylbenzene is distilled off and recycled to the extractor acetophenone is hydrogenated to methylbenzyl alcohol. Advantages of the ARCO process compared with the AO process are: cheap working solution, methylbenzyl alcohol is used both as solvent and as working compound and high hydrogen peroxide concentration in the working solution after oxidation.

4.3. Electrochemical Processes

Electrochemical production of hydrogen peroxide is of minor industrial importance compared to the AO process.

Because electrochemical processes played an important part in the development of hydrogen peroxide and their technology reached a high standard, essential features of the three known cyclic processes are described below. These processes are described in detail in [3, 5].

The basis of electrochemical processes is anodic oxidative coupling of sulfate ions to peroxodisulfate ions. Sulfuric acid is oxidized in the Degussa–Weissenstein process, whereas ammonium hydrogensulfate solutions are used in the Münchner process.

$$2\,H_2SO_4 \rightarrow H_2S_2O_8 + H_2$$

$$2\,(NH_4)\,HSO_4 \rightarrow (NH_4)_2S_2O_8 + H_2$$

Hydrogen peroxide is formed by hydrolysis of the peroxodisulfate ion via the peroxomonosulfate anion:

$$S_2O_8^{2-} + H_2O \rightarrow HSO_4^- + SO_3(OOH)^-$$

$$SO_3(OOH)^- + H_2O \rightarrow HSO_4^- + HOOH$$

In the Degussa–Weissenstein and Riedel–Loewenstein processes, peroxodisulfuric acid or ammonium peroxodisulfate derived from

Table 6. Yields and energy consumption of electrochemical processes

Yield or consumption*	Degussa–Weissen-stein process	Münchner process	Riedel–Loewenstein process
Current yield, %	73	83	83
Hydrolysis and distilla-tion yield, %	93–96	87	82–85
Total yield, %	68–70	72	68–70.5
Electrical energy, kW · h	1280	1760	1700
Steam, t	1.85	2.5	4.5–4.8
Cooling water, m^3	200	240	250

* Parameters are expressed per 100 kg of hydrogen peroxide (calculated as 100 wt %) in the form of a distilled 35 wt % solution.

the electrolysis is hydrolyzed directly. In the Münchner process, ammonium peroxodisulfate is converted to potassium peroxodisulfate, which is then hydrolyzed. The Münchner process, therefore, consists of several coupled cyclic processes.

All three processes have a very high energy consumption and an unsatisfactory yield of ca. 70 % (Table 6).

Huron developed a modified Loewenstein process, which makes use of platinum–titanium anodes and achieves a yield of 85 % [167]

4.3.1. Degussa–Weissenstein Process

In the Degussa–Weissenstein process (Fig. 14), sulfuric acid is adjusted to a concentration of 550–570 g/L (a) before flowing through the catholyte chamber (b) where residual peroxide is destroyed and heavy-metal ions are precipitated. After addition of chemicals to raise the electrochemical potential (e.g., ammonium rhodanide or hydrochloric acid), sulfuric acid passes to the anolyte chamber where peroxodisulfuric acid is formed. Hydrolysis of peroxodisulfuric acid and

Figure 14. Degussa–Weissenstein process
a) Electrolyzer feed tank; b) Electrolyzer; c) Evaporation and hydrolysis; d) Hydrogen peroxide expulsion and hydrolysis; e) Acid separator; f) Water–hydrogen peroxide fractionating column; g) Acid purification

distillation of hydrogen peroxide are carried out in two steps (c, d). Hydrolysis is 80–90 % completed in (c), and distillation is achieved in approximately equal parts in two steps (c, d). In the expulsion column (d), hydrogen peroxide is expelled from the concentrated sulfuric acid solution by countercurrent steam. Entrained acid is separated in an acid separator (e), and hydrogen peroxide–water vapors are separated in a fractionating column (f). An aqueous solution with a maximum content of 45 wt % hydrogen peroxide is obtained. To purify the circulating solution, part of the stream is distilled constantly (g).

4.3.2. Münchner Process

In the Münchner process (Fig. 15), acid ammonium sulfate is electrolyzed in electrolyzers without diaphragms.

The circulating solution contains 300 g of $(NH_4)_2SO_4$, 40 g of K_2SO_4, 100 g of H_2SO_4, and 57.6 g of $S_2O_8^{2-}$ per liter before entering the electrolyzer. Its peroxodisulfate concentration is increased to 115.2 g/L by the electrolytic process. After electrolysis, the circulating solution is cooled and concentrated in a vacuum cooler (b) by evaporation of water and then fed into a crystallizer (c). Half of the peroxodisulfate is precipitated as potassium peroxodisulfate by addition of potassium hydrogen sulfate and separated in a centrifuge (d). The supernatant mother liquor diluted with washing water is returned to the electrolyzer. Solid potassium peroxodisulfate is hydrolyzed (e) and hydrogen peroxide is steam distilled.

The remaining potassium hydrogensulfate–sulfuric acid residue is separated in a centrifuge (f). Sulfuric acid is recycled to the hydrolysis and distillation stage (e) via a purification stage (g). Potassium hydrogensulfate is returned to the crystallizer (c) for precipitation of peroxodisulfate.

To purify the circulating solution, a side stream is mixed with ammonia in the purification step (h) to precipitate iron. The hydrogen peroxide–water vapors formed during hydrolysis and distillation are led through an acid separator (i) and separated in the rectification step (j). Because hydrolysis is carried out batchwise, the initial vapor mixture is rich in hydrogen peroxide, giving a distillate of 60 wt % which then drops to 20 wt %.

4.4. Other Processes

A number of reactions and processes for the production of hydrogen peroxide are described in the literature. Some of them are no longer economical (e.g., the barium peroxide, azobenzene.

Only a few examples can be described here; detailed information may be found in the literature [1, 3, 5].

4.4.1. Production from Peroxy Compounds

Peroxy compounds can be decomposed to form hydrogen peroxide. Examples of such reactions, which include the historically important Thenard reaction of barium peroxide with nitric or sulfuric acid, are listed in Table 7.

Table 7. Production of hydrogen peroxide from peroxy compounds

Peroxide	Reaction	Reference
BaO_2	reaction of barium peroxide with H_2SO_4 in the presence of a small amount of HCl allows quantitative conversion; ca 6 % aqueous H_2O_2 solutions are obtained	[90]
BaO_2	as above, but in the presence of HCl and H_3PO_4	[91]
Na_2O_2	sodium peroxide solutions are passed through acidic ion exchangers to exchange Na^+ for H^+	[92]
$(CH_3)_3CO–OH$	*tert*-butyl hydroperoxide is hydrolized to *tert*-butanol and H_2O_2 in the presence of H_2SO_4 in a fractionating column	[93]
$(CH_3)_3CO–OH$	H_2O_2 and isobutene are formed from *tert*-butyl hydroperoxide in an aqueous medium in the presence of an acidic ion-exchange resin	[94]
	peracetic acid is hydrolyzed to CH_3COOH and H_2O_2 in the presence of H_2SO_4; to shift the equilibrium to H_2O_2, CH_3COOH is reacted with an alcohol and the ester is distilled	[95]
	peracetic acid is hydrolyzed with acidic ion exchangers, and the equilibrium mixture is separated by distillation	[96]

4.4.2. Production from Hydrogen and Oxygen

Hydrogen peroxide can be formed by direct reaction of oxygen and hydrogen. However, the

Figure 15. Münchner process
a) Electrolyzer; b) Vacuum cooler; c) Conversion (crystallization); d) Centrifuge; e) Hydrolysis–distillation; f) Centrifuge; g) Sulfuric acid purification; h) Purification of cycle solution; i) Acid separator; j) Fractionating column

most important hydrogen peroxide manufacturing process, the AO process, also allows production of hydrogen peroxide from the elements.

In 1935 [175] Pietzsch reported that silent electrical discharge into a gas containing 95 % hydrogen and 5 % oxygen in the presence of water vapor at 150–160 °C and 100 kPa, and subsequent condensation result in a 10 % aqueous solution of hydrogen peroxide. The power requirements are high (40 kWh per kilogram H_2O_2). Silent electrical discharge was proposed for producing ultrapure hydrogen peroxide for the semiconductor industry [176].

In 1985, DuPont developed and patented a new liquid-phase hydrogen peroxide process that directly combines hydrogen and oxygen and that allows a 50 % reduction in investment costs [177]. The DuPont patent [178] described the production of up to 25 % hydrogen peroxide solutions with a palladium on carbon catalyst in acidic aqueous solution containing halide ions as promoter at 10–25 °C and up to 17 MPa using an explosive oxygen/hydrogen gas mixture. The process was intensively investigated during the last two decades, a demonstration plant with a capacity of several kilotons of hydrogen peroxide in methanol is scheduled to be started up in the middle of 2006 [179]. For this direct combination of hydrogen and oxygen various catalytic systems, mostly with precious metals, were proposed. The process was especially investigated during the last decade, but has reached only pilot plant status. The ideal direct combination process should have:

1) High hydrogen peroxide production rate and low decomposition
2) A catalyst with long lifetime and minimal precious metal losses
3) Use of a non explosive gas mixture
4) Synthesis of hydrogen peroxide at low pressure and ambient temperature
5) Noncorrosive reaction medium
6) High hydrogen selectivity and hydrogen peroxide concentrations of at least 5 %

Heterogenous catalysts such as palladium or platinum or mixtures thereof on silica, alumina, charcoal or hydrophobic supports [180] or fixed-bed catalysts [181] are preferred. Fixing the catalyst on a halogenated resin eliminates dissolution of catalyst and corrosion of the equipment but results in low selectivity and product concentration [182, 183] Extremely high hydrogen selectivities (better than 90 %) using nonexplosive feedstreams can be reached with palladium on carbon black nanocatalysts [184].

To overcome the concerns over process safety while using explosive gas mixtures, special reactor designs are proposed: e.g., separately feeding hydrogen and oxygen into a completely liquid-filled tubular reactor [185], injecting dispersed minute bubbles of hydrogen and oxygen into a rapidly flowing liquid medium [186], or separately feeding very small bubbles of hydrogen and oxygen in the lower part of a mechanically agitated reactor in such a way that the molar ratio of hydrogen to oxygen falls within the explosive range but in the gas phase the ratio of the reactants lies outside this range [187]. Hydrogen peroxide concentrations as high as 20 % at hydrogen selectivities of 80–83 % can be reached. Use of methanol instead of water as reaction medium enables to lift the catalyst productivity from 207 to 879 gram H_2O_2 per gram catalyst per hour [188]. A vapour phase technique using a fluidized bed catalyst consisting of a thin layer (50 nm) of palladium on polytetrafluoroethylene is described [189, 190].

4.4.3. Production from Carbon Monoxide, Oxygen, and Water

Hydrogen peroxide can be formed from carbon monoxide, oxygen and water.

$$CO+O_2+H_2O \rightarrow H_2O_2+CO_2$$

The reaction was first described by Traube in 1884. Later palladium [191] or palladium phosphine and arsine complexes [192, 193] were used as catalysts, but the latter lacked oxidation stability. A palladium bathocuproine complex in a two-phase acidic solution should overcome these difficulties [194], but reaction pressure (5–7 MPa) and excess oxygen (ca. 10–20-fold) were high. The advantage of the process is that oxidation and reduction takes place in a single reactor. Improved catalyst stability is reported when using naphthoquinone as mediator [195]. The process is not used commercially.

4.4.4. Production by Autoxidation of Organic Compounds

Autoxidation processes for the production of hydrogen peroxide include the AO process and the 2-propanol process discussed in Sections Anthraquinone Process (AO Process) and 2-Propanol Process (Shell Process). A variation of the AO process is the use of H_2S instead of H_2 for the reduction of quinones [196, 197]. The azobenzene process has occasionally been used on a commercial scale. Analogous to the AO process, azobenzene is reduced to hydrazobenzene which is then oxidized to azobenzene. The reaction proceeds at alkaline pH and results in formation of $Na_2O_2 \cdot 8\ H_2O$ [198–200].

Other autoxidation processes have been suggested, such as the oxidation of hydrocarbons and alcohols, but they have no commercial significance. They are usually carried out in the gas phase at high temperature and give a multicomponent reaction mixture due to subsequent secondary reactions. Hydrogen peroxide can be also generated by the oxidation of hydrazine or hydroxylamine [201].

4.4.5. Production by Cathodic Reduction of Oxygen

The formation of hydrogen peroxide (max. 1 % solution) by cathodic reduction of oxygen was reported by Traube in 1882 [202]. The process was improved by Fischer and Priess who introduced pressurized electrolysis (ca. 10 MPa), which gave 1.3–2.7 % hydrogen peroxide solutions with current efficiencies of 83–90 % [203]. The cathodic reduction of oxygen can be described by the Equation (1).

$$O_2+H_2O+2\,e^- \rightarrow HOO^- + HO^- \quad (1)$$

Hydrogen peroxide is formed according to Equation (2).

$$HOO^- + H_2O \rightarrow H_2O_2 + HO^- \quad (2)$$

Side reactions are

$$HOO^- + H_2O + 2\,e^- \rightarrow 3\,HO^- \quad (3)$$

and

$$H_2O_2 - 2\,e^- \rightarrow O_2 + 2\,H^+ \quad (4)$$

Reaction (3) occurs at high current densities. To increase the space–time yield at low current densities, electrodes with high specific surface areas are used. Catalytic decomposition of hydrogen peroxide is avoided by using nonmetallic construction materials and limiting pH and temperature. The anodic decompostion (Eq. 4) is limited by using diaphragms or by controlling the anolyte flow. Oxygen evolved at the anode can be reused for cathodic reduction.

The first attempts to bring this process to technological maturity were made by Berl, followed by Kastening [204], and more recently by Huron and Dow (H-D Tech) [205–207] and others [208, 209]. An overview is given in [210, 211].

The Huron–Dow process seems to be the only one used on an industrial scale. It is intended for small on-site units, especially for the pulp industry. A unit with ca. 3000 t/a capacity has been operated since 1992 at Georgia Pacific in Muskogee/USA. The process uses a trickle-bed cathode and yields an alkaline solution with ca. 4 % hydrogen peroxide. The H_2O_2/alkali ratio is 1/1.7. The process is operated with an excess of $>$ 90 vol % oxygen near atmospheric pressure (ca. 0.11 MPa). A graphite/carbon black/teflon composite cathode with a lifetime of over one year is used, and the current yield is 80–95 %. The solution must have a minimum alkali concentration of 4 %; otherwise current yields are low.

For lowering the basicity of the hydrogen peroxide, combinations with dialysis cells are proposed [212]. Newer developments make use of fuel cell designs [213, 214]. While oxygen is reduced at the cathode, hydrogen at a pressure of 4.8–6.2 MPa is oxidized at the anode. No external power supply is needed, and alkaline-free hydrogen peroxide solutions with concentrations of up to 15 % can be produced.

5. Storage and Transportation [4]

The decomposition of hydrogen peroxide caused by catalytic impurities and the associated release of heat have been described in Chapters Physical Properties and Chemical Properties. Great care must be taken in production, storage, and transportation to prevent these impurities from entering the hydrogen peroxide solution and to ensure that hydrogen peroxide is put only into perfectly clean containers. Because commercial hydrogen peroxide always contains small quantities of catalytic impurities, the stabilization of peroxide solutions is extremely important. The stabilizing effects of inorganic and organic compounds are described in detail in [3].

Sodium pyrophosphate [*7722-88-5*] and sodium stannate [*12058-66-1*] are the preferred stabilizers and are added separately or together [215, 216]. Phosphonic- or aminophosphonic acids may also be used [217, 226].

Aluminum (99.5 %), aluminum–magnesium alloys, or stainless steels are good construction materials [218]. Because of their corrosion resistance, polyethylene containers and storage tanks are preferred for hydrogen peroxide concentrations up to 50 wt %. Before metallic tanks and containers can be used, their surfaces must be passivated. Iron particles may become attached to the surface during the rolling of aluminum, and they must be removed. Aluminum is therefore treated with dilute sodium hydroxide and then passivated with dilute nitric acid. Because hydrogen forms during the caustic treatment of aluminum with sodium hydroxide, safety precautions must be taken to avoid a detonating gas atmosphere. It is extremely important to ensure that no hydrogen peroxide is trapped, e.g. between closed valves. If decomposition occurs, ex-

tremely high pressures result which lead to very serious explosions.

Hydrogen peroxide is admitted for air transport only up to a concentration of 40 wt % (IATA regulations).

No special regulations apply to the transport of solutions of up to 8 wt % hydrogen peroxide. Table 8 lists international regulations for rail (RID), road (ADR), and sea (IMDG code) transport of more highly concentrated solutions.

6. Safety

Hydrogen peroxide has a high energy content:

$$H_2O_2\,(l) \rightarrow H_2O\,(l) + 1/2\,O_2\,(g)\ \Delta H = -98.30\,\mathrm{kJ/mol}$$

Furthermore, its high oxygen content (47 wt %) is available for combustion reactions and the oxidation of organic compounds. This means that special safety conditions apply in handling hydrogen peroxide [219, 232]. Safety studies can be divided into three groups:

1) Examination of the pure vapor phase,
2) Examination of the pure liquid (aqueous) phase, and
3) Examination of mixtures or solutions of organic compounds with or in aqueous hydrogen peroxide.

Results are summarized below, but the literature must be consulted for details. In specific cases, especially when hydrogen peroxide is used with organic compounds, the intended work area must be checked for hazards if it has not already been certified as safe by a safety examination.

Pure Hydrogen Peroxide — Vapor Phase [5, 220–223]. Explosive vapor mixtures are formed at atmospheric pressure when the hydrogen peroxide concentration in the vapor phase exceeds 26 mol %. Figure 16 shows the explosive range as a function of temperature and hydrogen peroxide concentration.

For the industrial concentration of hydrogen peroxide solutions, it is important to note that at reduced pressure the critical hydrogen peroxide concentration of the vapor phase may exceed 26 mol % (Fig. 17).

Figure 16. Dependence of the explosive range of the vapor phase (> 26 mol % H_2O_2) on the temperature and the hydrogen peroxide concentration of liquid phase (at atmospheric pressure)

Figure 17. Dependence of the explosive range of vapor phase on pressure

Pure Hydrogen Peroxide — Liquid (Aqueous) Phase [224–226]**.** The explosive risk of pure, highly concentrated hydrogen peroxide solutions has been examined by various methods, but the sometimes contradictory findings are difficult to interpret consistently.

Results are influenced primarily by test conditions and not by hydrogen peroxide concentration. For example, 90.7 wt % hydrogen peroxide in a tube with an internal diameter of 2.67 cm (1.05 inches) could not be exploded by the detonation shock of a tetryl booster, whereas explosion occurred in a tube with an internal diameter of 4.09 cm (1.61 inches). Similarly, 86 % hydrogen peroxide in a tube of 4.09 cm internal diameter was exploded by raising the temperature above 50 °C [224, 225]. The decisive factors for explosion of pure aqueous hydrogen peroxide seem to be the degree of occlusion, the insulation, and the energy of detonation.

Mixtures or Solutions of Aqueous Hydrogen Peroxide with Organic Compounds [219, 227–234]**.** The hazards associated with mixtures of hydrogen peroxide and organic chemicals are important for its industrial production and, especially, for its uses. As an example, Figure 18 shows results obtained with the hydrogen peroxide–acetone–water system [227]. Many other organic compounds give similar results. The size of the explosive region depends on the organic compound and the test conditions.

Figure 18. Explosive range (hatched area) of hydrogen peroxide–acetone–water mixtures
Dashed line, indicates the stoichiometry
$8\,H_2O_2 + CH_3COCH_3 \rightarrow 3\,CO_2 + 11\,H_2O$

For practical use, safety tests of the intended working area are very important. When systems such as hydrogen peroxide–formic acid–water are used, other products may be formed (in this case performic acid), that are more dangerous than the original mixture [228].

7. Uses

Development of the AO process permitted large-scale production of hydrogen peroxide, which is now used widely in almost all industrial areas. Its main use is in bleaching (→ Bleaching, Chap. 2.2.3). Uses in the chemical industry and in environmental protection are increasing because its great advantage is that the degradation product is water.

Hydrogen peroxide is used in the textile industry for bleaching cotton, linen, bast fibers, wool, silk, polyester fiber, and polyurethane fiber. In the pulp and paper industry, it is used to bleach sulfate and sulfite cellulose, wood pulp, and wastepaper, and to brighten wood veneers and wooden structures.

The chemical industry employs hydrogen peroxide for the production of peroxy compounds such as sodium perborate, sodium percarbonate, metallic peroxides, or percarboxylic acids. Hydrogen peroxide is very important in organic chemistry [229] for epoxidation and hydroxylation (manufacture of plasticizers and stabilizers for the plastics industry), oxidation (manufacture of amine oxides as surfactants for detergents), oxohalogenation, and initiation of polymerization. BASF and Dow Chemical have developed a cost-effective process for production of propylene oxide using hydrogen peroxide; the first commercial plant with a capacity of 300 000 t/a of propylene oxide using this new technology is scheduled to go on stream early 2008 [234].

Sulfuric acid solutions of hydrogen peroxide are used for the pickling and chemical polishing of copper, brass, and other copper alloys, as well as for etching and cleaning printed circuit boards. Highly purified hydrogen peroxide is used in wet chemical processes during the manufacture of silicon semiconductor devices to clean silicon wafers and to remove photoresist layers. It is also used for in situ leaching in underground uranium mining.

Hydrogen peroxide is increasingly used in environmental protection to detoxify effluents containing formaldehyde, phenols, or cyanide (e.g., wastewater from mines and tempering works, galvanizer concentrate, photochemical effluents), and to deodorize sulfur-containing effluents. Smoke and exhaust gases containing sulfur dioxide and even dioxins can be completely detoxified with hydrogen peroxide.

Hydrogen peroxide is a highly efficient disinfectant (especially for packaging materials); it is also used as a bleaching agent in hair preparations and as a propellant [226] in space technology.

8. Toxicology and Occupational Health

Hydrogen peroxide plays a major role in physiological oxidation processes in living organisms. Hydrogen peroxide is produced during normal aerobic cell metabolism, which involves a number of enzymes, in particular superoxide dismutase. Humans may exhale up to 1 mg/m3 of hydrogen peroxide resulting from endogenous formation [236].

Reactive oxygen species, including hydrogen peroxide, may also lead to oxidative damage to cells. Therefore a number of defense systems can be found in biological systems which lead to detoxification of reactive oxygen species. The most important detoxification reactions for hydrogen peroxide are its conversion to oxygen and water by enzymes such as catalase, peroxidase, and selenium-dependent glutathione peroxidase. The activity of these enzymes varies between tissues and between different animal species or strains [236]. Additionally, a variety of nonenzymatic antioxidants, such as Vitamin E and A, ubiquinols, ascorbic acid, glutathione, complete an efficient intra- and extracellular network of defenses [237].

There is limited information concerning the absorption of exogenously applied hydrogen peroxide. The permeability of biological membranes to hydrogen peroxide is comparable to that of water, but less than that of oxygen [236].

Although significant amounts of topically applied hydrogen peroxide can penetrate the epidermis or mucous membranes, the substance undergoes rapid spontaneous or enzyme-catalyzed decomposition to water and oxygen in the underlying tissue. This may lead to the formation of small gas bubbles and reversible blanching of the exposed tissue. Formation of larger volumes of gaseous oxygen can lead to detachment of cell layers and the rupture of tissues and organs. Locally formed oxygen is removed by the blood. However, the increase in oxygen content in the blood results in a hyperbaric response. There is no evidence that hydrogen peroxide itself is absorbed in amounts sufficient to produce systemic effects [236]. In in vitro studies with rat blood plasma additions of up to 1 mM of hydrogen peroxide were degraded to nondectable concentrations within less than 10 min [238]. This experimental result supports the assumption that hydrogen peroxide is not systemically available.

The major adverse effects of hydrogen peroxide are related to its irritating properties.

The acute oral toxicity of hydrogen peroxide in animals depends on the strength of its solution. In the rat LD_{50} values ranged from $>$ 5000 mg/kg for a 10 % solution to 1200 mg/kg for 35 % solution. In humans, toxic effects observed after accidental ingestion of concentrated solutions are generally related to the irritant or corrosive action and the rapid generation of large volumes of oxygen in the gastrointestinal tract. Single cases of deaths due to gas embolism following accidental swallowing of hydrogen peroxide solutions have been reported [239], however, in other case reports complete recovery was observed within 2-3 weeks [236].

Complete recovery has occurred within two to three weeks even in near fatal cases [236].

Effects of exposure to hydrogen peroxide by inhalation are limited to irritation of the respiratory tract and the eyes. Exposure to hydrogen peroxide vapor (338–427 mg/m^3) induced signs of irritation in rodents. In humans exposed for 4 h the irritation threshold for the respiratory tract was 10 mg/m^3 and for the skin 20 mg/m^3. At these concentrations, eye and throat irritation were reported [236].

Slight nasal irritation was reported in factory workers for short-term exposure to ca. 3.5 mg/m^3 [236]. Gradual bleaching of hair was reported for exposure levels of 0.7–1.4 mg/m^3, but it was uncertain whether bleaching was due to vapor exposure or to transfer of hydrogen peroxide from the hands (gloves) to the hair [236].

The dermal toxicity of hydrogen peroxide solutions of 35–75 % in rabbits was low (LD_{50}, dermal, rabbit: > 2000 mg/kg). LD_{50} values of a 90 % solution ranged from ca. 690 mg/kg in rabbits to > 2000 mg/kg in rats, pigs, and cats [236].

The irritating properties of hydrogen peroxide are dependent on the concentration of the solution. Hydrogen peroxide solutions of 10 % or less were nonirritating, and solutions of 35 % slightly irritating to rabbit skin. Higher concentrations (≥ 50 %) are corrosive to rabbit skin. Hydrogen peroxide (50 %) was corrosive to rabbit skin after 1 h of exposure, whereas 70 % hydrogen peroxide showed corrosive effects after only 3 min of exposure [236]. Dermal exposure of humans to dilute solutions has been reported to result in transient symptoms without permanent effects, such as paresthesia, blanching, and blistering [236].

With regard to eye irritation solutions of 5 % or less are not irritant to rabbit eyes; a concentration of 6 % caused slight reversible eye irritation in rabbits. Concentrations of 10 % or higher caused irreversible corneal damage. In humans, 1–3 % solutions have been used for eye treatment without causing injury. However, solutions containing more than 200 mg/L have been reported to cause hyperemia, and concentrations of greater 100 mg/L transient pain and stinging [236]. Hydrogen peroxide (6 %) was not a skin sensitizer in guinea pigs [236]. Human experience from dermatological hospital departments confirms that hydrogen peroxide is no skin sensitizer [239].

After repeated inhalation exposure (6 h/d, 2 to 3 d per week, 3 weeks), mortality in mice was observed at 80 mg/m^3 hydrogen peroxide. After prolonged exposure, in rats and dogs (5 or 6 h/d, 5 d per week for 16 or 26 weeks, respectively), respiratory irritation and transient skin thickening were observed at 10 mg/m^3 hydrogen peroxide [236]. In a 28-day inhalation study in rats the NOAEL for respiratory tract irritation was 2.9 mg/m^3. Clinical signs of irritation were observed from 14.6 mg/m^3 [240].

In humans, pulmonary function monitoring showed no evidence of adverse effects from occupational exposure for several years at levels ranging from not detectable to 0.79 mg/m^3 (8-h TWA) [236]. Further surveys of workers occupationally exposed to hydrogen peroxide in different production plants for up to 40 years with recent exposures below 1.4 mg/m^3 (8-h TWA), but occasional peak exposures up to 5 mg/m^3 confirmed the absence of effects on lung function or any other clinical effects apart from single observations of skin or throat irritation, skin or hair whitening after acute incidents of high short-term exposures [239]. In a population exposed to levels of 2 - 3 mg/m^3 (8-h TWA) and frequent peak exposure levels up to 11 mg/m^3 symptoms including eye and respiratory irritation, headaches and temporary loss of olfaction as well as skin and hair blanching and three cases of recurring bronchitis–sinusitis were reported. All persons recovered completely after the exposure was reduced to below the occupational exposure limit of 1.4 mg/m^3 and the repeated peak exposures were avoided. The authors assume that the recurrent peak exposure levels of up to 11 mg/m^3 may have contributed to the observed symptoms [241].

More detailed studies of the effects of hydrogen peroxide after prolonged exposure were performed by administration in drinking water. After prolonged exposure (146 d), decreased bodyweight gain was observed in rats at concentrations of 0.25 % and above [242] (other studies observed first effects at higher levels [236]).

In a 90-d drinking water study in catalase-deficient mice receiving 100–3000 ppm of hydrogen peroxide, irritation of the mucous membranes of the gastrointestinal tract was observed. The no observed adverse effect level (NOAEL) was 100 ppm, corresponding to 26 and 37 mg kg^{-1} d^{-1} for male and female mice, respectively. After cessation of treatment these effects were fully reversible. No systemic effects were observed [243]. In studies on the same mouse strain with a 6–7 month exposure period, signs of gastrointestinal irritation were observed at approximately the same dose level as in the 90-d study. Therefore it can be assumed that the effect is not cumulative and the NOAEL does not decrease with increasing exposure time. A NOAEL of 56.2 mg kg^{-1} d^{-1} was reported in a 12-week gavage study in rats [236].

Results of mutagenicity studies indicate that hydrogen peroxide induces gene mutations in vitro without metabolic activation in bacteria, yeast, and mammalian cells. Hydrogen peroxide also induced chromosome aberrations and micronuclei in mammalian cell cultures without

a metabolic activation system. However, addition of exogenous metabolic activators or catalase lowered or abolished the genotoxic response [236]. In a mechanistic study, it has be shown that hydrogen peroxide induced controlled cell death (apoptosis) rather than genotoxic lesions in cell cultures of human lymphocytes and did not induce 8-hydoxyguanosin formation [244].

In *in vivo* tests, no chromosomal aberrations or micronuclei were observed in the bone marrow of rats and mice after repeated oral or single intraperitoneal administration [236]. An in vivo/ex vivo study for unscheduled DNA synthesis (UDS) after intravenous administration of the maximum tolerated dose to rats did not show an increase in UDS compared to the solvent control group [245]. In a study of local genotoxicity to mouse skin, 70 % hydrogen peroxide did not cause any mutations, hydroxylation of DNA bases, or gave an indication of cellular proliferation, thus suggesting that the substance has no local genotoxic potential in vivo [239]. In conclusion, the available studies indicate that hydrogen peroxide has no genotoxic or mutagenic potential under *in vivo* conditions.

The carcinogenic effects of hydrogen peroxide were studied in rats and mice. Hydrogen peroxide induced an increase of duodenal tumors in mice chronically exposed to 0.1–0.4 % of hydrogen peroxide in drinking water. The tumor incidence correlated with a specific inflammatory response in this tissue and was more pronounced in those mice strains which had a low catalase activity [236]. The absence of preneoplastic changes and the reversibility of the effects in a 90-d drinking water study in mice of the same strain [243] (with 0.01–0.3 % hydrogen peroxide in drinking water), suggest that the tumors observed in the two-year study seem to be a secondary response to a prolonged inflammatory process in this specific strain of mice. Rats exposed to near lethal concentrations in their drinking water developed forestomach papilloma but no tumors in the glandular stomach and duodenum [236]. Chronic hydrogen peroxide exposure at concentrations which induce significant inflammation of the exposed tissue has been shown to give a weak tumor-promoting effect. Repeated topical application of 15 % hydrogen peroxide to Sencar mice did not induce skin tumors; this demonstrates the absence of initiating properties [236].

On the basis of these studies ACGIH has grouped hydrogen peroxide into category A3 for carcinogenicity: "The agent is carcinogenic in experimental animals at relatively high doses, by routes of administration, at sites of histological types, or by mechanisms that are not considered relevant to worker exposure. Available epidemiological studies do not confirm an increased risk of cancer in exposed humans. Available evidence suggests that the agent is not likely to cause cancer in humans except under uncommon or unlikely routes of exposure" [246]. Similar conclusions were drawn in the EU risk assessment on hydrogen peroxide [239].

Occupational exposure limits have been established for hydrogen peroxide in different countries, for example by ACGIH [246], the Dutch Social Economic Council [247], the UK HSE [251], Belgium [248], the French Ministry of Labour [249], and the German AGS (Ausschuss für Gefahrstoffe) [250]: 8-h TWA: 1.4 mg/m^3 or 1.5 mg/m^3. A 15-min STEL of 2.8 mg/m^3 was established by HSE (max. 1 h in a 24-h period) [251], and a 15-min STEL of 1.4 mg/m^3 by AGS [250].

9. Environmental Effects

Hydrogen peroxide occurs naturally. Its formation, use, and degradation are strongly related to the oxygen-containing atmosphere of our planet and adaptation of nature to oxygen. The concentration of hydrogen peroxide in environmental compartments results from a dynamic equilibrium between its natural production and degradation in photochemical, chemical, and biological processes.

Because of its chemical reactivity, hydrogen peroxide also has toxic properties that are sometimes used as a natural defense mechanism. The toxicity of hydrogen peroxide to organisms and cells is dependent on the balance of intoxication and detoxification. However, detoxification reactions can in turn lead to toxic effects due to the release of oxygen gas [252].

9.1. Atmospheric Fate

The atmospheric fate of hydrogen peroxide is governed by generation and degradation reactions. The formation of atmospheric hydrogen

peroxide is photochemically mediated. Consequently, natural concentrations are latitude-dependent. High solar irradiation leads to high hydrogen peroxide concentrations. Hydrogen peroxide in atmosphere is produced through radical reactions. Light, oxygen, hydrocarbons, and free radicals in the atmosphere mediate hydrogen peroxide formation.

In an unpolluted atmosphere, the formation of H_2O_2 is ultimately due to the photolysis of ozone (O_3) at wavelengths < 310 nm to give oxygen atoms. The latter are converted to free radical species, including $^{\bullet}OH$, $RO^{\bullet}$, $HO_2^{\bullet}$, and $RO_2^{\bullet}$, which initiate the breakdown of organic species and give rise to $HO_2^{\bullet}$ radicals which are precursors of H_2O_2 [253]. The superoxide radical $O^{2-\bullet}$ is the direct precursor of H_2O_2:

$$2\,O^{2-\bullet}+2\,H^{+}\rightarrow H_2O_2+O_2$$

The rate of H_2O_2 formation from $O^{2-\bullet}$ is of the second order and is also temperature- and humidity-dependent. Levels of H_2O_2 were raised by 70 % when air temperature increased from 10 to 30 °C, other factors remaining constant [254].

Water vapor is involved in another process of H_2O_2 formation, namely, the production of hydrated hydroperoxyl radicals, which rapidly react with $HO_2^{\bullet}$ radicals to generate H_2O_2. About twice as much H_2O_2 is formed at 100 % relative humidity than at 50 % humidity at ambient temperature (25 °C) [255].

Degradation in the atmosphere is due to direct and indirect photolysis reactions and to chemical reaction with organic substances. Degradation by indirect photolysis is expected to be the main degradation mechanism in air. Indirect photolysis is due to sensitization by secondary reactions with OH and O_2 radicals and organic substances. The most important degradation reaction is reaction with the hydroxyl radical:

$$H_2O_2+{}^{\bullet}OH\rightarrow H_2O+HO_2^{\bullet}$$

Direct hydrogen peroxide photolysis is mediated by radiation at wavelengths of 280–380 nm:

$$2\,H_2O+h\nu\rightarrow H_2O+{}^{\bullet}OH+HO_2^{\bullet}$$

$$^{\bullet}OH+HO_2^{\bullet}\rightarrow H_2O+O_2$$

The rate for the direct photolysis of hydrogen peroxide for moderate light intensities is directly proportional to the hydrogen peroxide concentration and the square root of the light intensity [256]. Kleinman estimated the direct photolysis half-life to be 2.14 days [257].

The formation of organic hydroperoxides (R−OOH) appears to be another pathway for the decomposition of H_2O_2 in the atmosphere. They are formed by hydroxy radical induced oxidation of hydrocarbons or direct oxidation of aldehydes by hydrogen peroxide:

$$R-CHO+H_2O_2\rightarrow R-OOH$$

However, the measured levels of R−OOH have been reported to be only 1 to 10 % of the ambient air concentrations of hydrogen peroxide [258].

The overall tropospheric half-life of hydrogen peroxide was reported to be 10 to 20 h [257]. Atmospheric levels of hydrogen peroxide ranged from 0.02 ppb to 4 ppb in unpolluted air and up to 180 ppb in smog situations. Concentrations in rainwater ranged from 0 to approximately 2000 µg/L, cloud water contained up to 8000 µg/L [252].

9.2. Aquatic Fate

Hydrogen peroxide levels in natural waters range from 0.14 to 58 µg/L in seawater and from 0.34 to 109 µg/L in freshwater [252]. The concentrations are dependent on the daytime and sunlight intensity and are decreasing with increasing depth. In surface water a photochemical process involving dissolved, light-absorbing organic matter (e.g., humic acids) and molecular oxygen produces hydrogen peroxide. The wavelengths needed are between 290 and 385 nm [256, 259, 260].

$$\text{Organic matter}+h\nu\rightarrow \text{Organic radical}^{\bullet}$$

$$\text{Organic radical}^{\bullet}+O_2\rightarrow \text{Organic radical}^{+\bullet}+O_2^{-}$$

$$2\,O_2^{-\bullet}+2\,H^{+}\rightarrow H_2O_2+O_2$$

In seawater, the Weiss mechanism also contributes to the formation of hydrogen peroxide [261].

$$Fe^{2+}+O_2\rightarrow Fe^{3+}+O_2^{-\bullet}$$

$$Fe^{2+}+O_2^{-\bullet}+2\,H^{+}\rightarrow Fe^{3+}+H_2O_2$$

Hydrogen peroxide concentrations in surface water can also originate from precipitation of rain [259].

9.3. Biodegradation

The main source of degradation of hydrogen peroxide in natural waters is the degradation by biological material, e.g., plankton. The half-life in water decreases with increasing size of the microbial population in water [252].

Consequently, the half-life in natural waters was reported to range from a few hours to several days [262]. Degradation is also catalyzed by transition metals. This may in particular play a role for the more rapid degradation in seawater. Direct photolysis does not play a major role in aquatic decomposition.

In municipal wastewater, hydrogen peroxide degrades rapidly because of the content of microorganisms and organic material. Half-lives were reported to be below 15 min [263]. Half-life was reported to be below 2 min in an activated sludge respiration test according to OECD guideline 209 [252].

9.4. Environmental Releases

Environmental releases of hydrogen peroxide, in particular to surface water, can occur during production and use. Where there is no wastewater treatment, higher concentrations may be released that may lead to toxicity to aquatic organisms. A review of the environmental releases from different production and use scenarios is given in the EU risk assessment of hydrogen peroxide [239].

9.5. Environmental Effects

Hydrogen peroxide is moderately toxic to aquatic organisms. For hydrogen peroxide, acute ecotoxicity data are available for three aquatic tropic levels (fish, daphnia, and algae). The toxicity of hydrogen peroxide to salt water species was of the same order of magnitude as that to freshwater species. The 96-h LC50 values for freshwater fish range from 16.4 to 37.4 mg/L H_2O_2 [252]. The 48-h EC50 value for *Daphnia pulex* was 2.4 mg/L and the 24-h EC50 for *Daphnia magna* was 2.3 mg/L [239].

For algae, the initial algae concentration influences the outcome of the study. The most appropriate studies are those with the OECD standard of 10 000 cells/mL at the moment of addition of hydrogen peroxide. Under these conditions, the 72-h EC50 (biomass) in the green algae *Chlorella vulgaris* was 2.5 mg/L, based on growth rate the 72-h EC50 was 4.3 mg/L [265]. Other algae species were less sensitive, for example the 96-h IC50 for *Scenedesmus quadricauda* was 27.5 mg/L [266].

For the bacterium *Pseudomonas putida*, a 16-h EC_{10} of 11 mg/l was determined [252]. At concentrations from 30 mg/mL (no observed effect concentration in an activated sludge respiration inhibition test), some toxicity to degrading microorganisms has been observed, the EC_{50} was 466 mg/L in this study [264]. However, at concentrations up to 200 mg/L, H_2O_2 does not affect the performance of biological treatment works (activated sludge process). It has even been shown to stimulate the biodegradation in wastewater treatment works [252].

Chronic toxicity studies on standard fish and daphnia species are not available, but studies on different life stages of fish [267] and prolonged (56-d) exposure of zebra mussels [268] do not indicate effects of higher sensitivity than in acute studies. The lowest long-term aquatic no-effect concentration (NOEC) was 0.1 mg/L in *Chlorella vulgaris* [265]. In a field study, the influence of hydrogen exposure on phytoplankton and bacterioplankton in a small humic lake in Canada has been examined. At H_2O_2 concentrations above 3.4 mg/L, both phytoplankton and bacterioplankton were inhibited. Bacteria were inhibited at concentrations between 0.12 and 3.4 µg/L. Photosynthetic activity of phytoplankton was increased at concentrations between 3.4 and 34 µg/L. Interestingly, the toxicity to phytoplankton was dependent on the time of the day. During the period of lowest background H_2O_2 concentrations at sunrise, no effect was observed even when concentrations as high as 170 µg/L were added. At sunset, a concentration of 1.7 µg/L resulted in a decrease of primary production by algae suggesting that the detoxification capacity of the cells might have been exceeded because of the higher natural concentrations [269].

The effect of hydrogen peroxide to plants has been tested on growth, seed germination, and early seed growth of rice, corn, soybean, pigweed, tomatoes, and barnyard grass. Concentrations up to 218 mg/L in irrigation water have no

significant effect on any of the above parameters [252].

When assessing the risk of hydrogen peroxide to environmental organisms, the background concentrations in the environment and the capacity to adapt to increased hydrogen peroxide concentrations have to be considered. The medium used in laboratory tests is quite different from the natural conditions. Depending on the environmental conditions, many materials (e.g., dissolved transition metals, solid metals, solid metal oxides, hydroxides, activated carbon, enzymes) may contribute to rapidly reduced hydrogen peroxide levels. It is thus assumed that under laboratory conditions the test organisms are more exposed and thus more sensitive than under natural conditions to the prolonged exposure of H_2O_2. In field conditions, the more sensitive species may also be protected from a direct effect of hydrogen peroxide by the presence of the total biomass and the suspended solids.

However, it is obvious that accidental releases, in particular of highly concentrated hydrogen peroxide, can immediately be lethal to aquatic organisms. With regard to long-term effects of lower levels, it can be expected that adaptation of ecosystems may well be possible.

1. Introduction

Hydrogen sulfide was first described as a natural compound by alchemists in the Middle Ages. The successful development of the sour gas field at Lacq (France) by the Société Nationale des Pétroles d'Aquitaine in 1957 modified the economy of hydrogen sulfide and allowed worldwide exploitation of natural gas with a high hydrogen sulfide content. Before this, hydrogen sulfide was regarded as a toxic, corrosive component of natural gas that had to be eliminated. However, it has now become an important raw material for producing sulfur and thioorganic compounds.

Some of the data and indications given are the result of Elf Aquitaine's experience, either from the Lacq field or from various gas and oil desulfurization plants that the company has built around the world.

Natural Occurrence The quantity of hydrogen sulfide naturally released into the atmo-

sphere is thought to vary annually from 100×10^6 to 324×10^6 t [1–3], with half of this coming from volcanoes [4,5], flooded ground [6–9], or hydrogeological sources [10,11] and the other half from oceans [12,13].

Hydrogen sulfide has been identified in the atmosphere of stars by spectroscopic methods. Calculations have been made of the thermal equilibrium of chemical species found in the atmosphere of several planets [14].

Hydrogen sulfide is present as an occluded gas in minerals such as topaz, tourmaline, water chrysolite, obsidian, and granite. The hydrogen sulfide found in ore-bearing deposits may originate from bacteria: its reducing properties account for the presence of uranium in the form of nonoxidized mineral deposits.

Salt mines also contain hydrogen sulfide, sometimes mixed with other gases. Volcanoes release large quantities of hydrogen sulfide in the fumaroles, and in gases and vapors produced from solfataras.

Flooded ground (swamps, rice fields) also contains hydrogen sulfide which is generally formed in the soil by bacterial reduction of sulfates. However, its occurrence may also depend on the type of soil, the presence of organic material, and the degree of aeration.

Water is another natural medium that contains hydrogen sulfide. The dissolved or gaseous hydrogen sulfide found in lakes, saltwater ponds, and marine sediments originates from sulfate-reducing bacteria. Mineral waters from thermal springs are studied either in vitro, to examine sulfate reduction by bacteria, or in situ, where the hydrodynamic effects (water velocity in soil, mineralization, and temperature) are coupled with the biological production of hydrogen sulfide. Wastewater of industrial [15] or other origin [16,17] often contains hydrogen sulfide.

Finally, hydrogen sulfide is found in hydrocarbon reserves: natural gas, associated gas, and oil. An extensive bibliography exists on this subject. Further information on particular reservoirs can be found in the following references: Federal Republic of Germany [18,19]; Lacq (France) [20,21]; Astrakhan (former Soviet Union) [22–32]; Orenbourg (former Soviet Union) [33–41]; United States [42, ; gives the composition of 349 reservoirs]; and People's Republic of China [43] (reservoir containing the highest known percentage, i.e., 90 %, of hydrogen sulfide). Problems encountered in the development of very sour oil or gas fields are also discussed in the literature: avoidance of formation of SO_4^{2-} in edgewater [44]; tools for studying hydrogen sulfide wells [45,46]; neutralization of hydrogen sulfide during drilling [47–52]; and reserves located at great depth [53] or under high pressure [19].

2. Physical Properties

Hydrogen sulfide [*7783-06-4*], H_2S, is also known as monosulfane, M_r 34.08. The gas is colorless, heavier than air, and has a characteristic rotten-egg odor.

Physical properties are listed below:

bp (101.3 kPa)	−60.28 °C
Triple point (23.2 kPa)	−85.49 °C
Critical temperature	100.25 °C
Critical pressure	8.96 MPa
Critical density	347.62 kg/m^3
Density of solid [54] at	
−195 °C	1.217 kg/m^3
−170 °C	1.166 kg/m^3
Density of liquid [55] at	
bp	949.0 kg/m^3
−30 °C	893.8 kg/m^3
9.7 °C	813.8 kg/m^3
90.4 °C	532.6 kg/m^3
Density of vapor [55] at	
−80 °C	0.71 kg/m^3
bp	1.99 kg/m^3
−30 °C	6.82 kg/m^3
56.9 °C	71.65 kg/m^3
Vapor pressure of [55] at	
−30 °C	0.381 MPa
0 °C	1.032 MPa
30 °C	2.275 MPa
60 °C	4.335 MPa
Viscosity of vapor (101.3 kPa) [56] at	
0 °C	0.01179 mPa · s
15 °C	0.01241 mPa · s
50 °C	0.01398 mPa · s
100 °C	0.01608 mPa · s
Viscosity of liquid (101.3 kPa) [57] at	
−11.5 °C	0.00169 mPa · s
15 °C	0.00133 mPa · s
30 °C	0.00116 mPa · s
50 °C	0.00094 mPa · s
Surface tension at	
−60.2 °C [58]	25.43 kN/m
25 °C [59]	11.3 kN/m
40 °C [59]	8.7 kN/m
Refractive index (n_D^0) of gas at 0.1 MPa and 0 °C [60]	1.000644
Dipole moment [61]	3.269×10^{-30} C · m (0.98 debye)
Latent heat of fusion	2.378 kJ/mol

Flammability limits in air (20 °C and 101.3 kPa) [63]	
Lower	4 vol %
Upper	44 vol %
Autoignition temperature	
at 101.3 kPa	290 °C
Thermal conductivity of gas (101.3 kPa) [64] at	
0 °C	1.340 kJ m^{-1} s^{-1} K^{-1}
80 °C	1.784 kJ m^{-1} s^{-1} K^{-1}
120 °C	2.010 kJ m^{-1} s^{-1} K^{-1}
200 °C	2.433 kJ m^{-1} s^{-1} K^{-1}

Compressibility factors of hydrogen sulfide gas and liquid are given in Table 1. The latent heat of vaporization and specific heat of the liquid are listed in Table 2. Table 3 gives specific heats of hydrogen sulfide gas. The solubilities of hydrogen sulfide in water and some organic solvents are listed in Table 4.

Table 1. Compressibility factor z of gaseous and liquid hydrogen sulfide [55]

3. Chemical Properties

3.1. Acid Properties

Hydrogen sulfide in aqueous solution is a weak acid with two dissociation constants:

$$H_2S \rightleftharpoons HS^- + H^+ \qquad K_1 = 10^{-7}\ (18\,^\circ\mathrm{C})$$
$$HS^- \rightleftharpoons S^{2-} + H^+ \qquad K_2 = 10^{-13} - 10^{-14}$$

Saturation of the first acid function with sodium hydroxide solution is an exothermic reaction:

$$NaOH + H_2S \longrightarrow NaSH + H_2O \qquad \Delta H = -36.7\ \mathrm{kJ/mol}$$

Hydrogen sulfide can precipitate salts of heavy metals (Hg, Pb, Ag, Bi, Cu, Cd, As, Sb, Sn, Co, Ni, Fe, Zn, Mn, Al) as sulfides. It dissolves and reacts with amines and can be released by heating. Numerous processes for removing hydrogen sulfide from natural gas (i.e., gas sweetening processes) are based on its absorption by amines (see Chap. 5).

3.2. Reducing Properties

The standard redox potentials of hydrogen sulfide at 25 °C follow [69]:

$$S + 2H^+ + 2e^- \rightleftharpoons H_2S \qquad E^0 = +0.14\ \mathrm{V}\ (\mathrm{pH} = 0)$$
$$S + 2e^- \rightleftharpoons S^{2-} \qquad E^0 = -0.48\ \mathrm{V}\ (\mathrm{pH} = 14)$$

At pH 0, hydrogen sulfide is barely dissociated; at a pH of ca. 12, partial dismutation modification of the oxidation level of sulfur can occur and the sulfide is oxidized to form oxygen–sulfur compounds.

Hydrogen sulfide reacts with numerous oxidizing agents to form sulfur compounds with varying degrees of oxidation. Depending on operating conditions and the oxidizing species concerned, sulfur oxides (SO_2, SO_3), salts ($S_2O_3^{2-}$, SO_3^{2-}, SO_4^{2-}), polythionic compounds, sulfur, and sulfanes are obtained.

1) Aqueous solutions of hydrogen sulfide can be oxidized in air.
2) In air, solutions of ammonium sulfide form orange polysulfides and even oxygen – sulfur compounds.
3) In an acid medium, iodine quantitatively oxidizes hydrogen sulfide to sulfur. This reaction is used to analyze hydrogen sulfide.
4) Strong oxidizing agents (e.g., MnO_4^-, ClO^-, Cl_2, and Br_2) react with hydrogen sulfide to give sulfate ions.
5) Hydrogen sulfide can react with sulfur to form sulfanes. The sulfanes can be converted back to hydrogen sulfide by base catalysis [70].
6) Hydrogen sulfide or alkaline hydrosulfides can reduce polysulfides to thiols [71]:

$$R-S-S-R + 2\,NaSH \longrightarrow 2\,RSH + Na_2S_2$$

This reaction is used for the preparation of thiokol polymers.

7) Hydrogen sulfide can reduce sulfoxides to sulfides [72]:

$$R-SO-R + H_2S \longrightarrow R-S-R + H_2O + S$$

8) The reaction of hydrogen sulfide and sulfur dioxide (Claus reaction) is used for the production of sulfur (→ Sulfur):

$$2\,H_2S + SO_2 \longrightarrow 3/8\,S_8 + 2\,H_2O$$

3.3. Reactions with Organic Compounds

Hydrogen sulfide reacts with numerous organic compounds directly, as an intermediate (e.g., sodium, potassium, or ammonium hydrosulfide), or as an alkaline sulfide.

Hydrogen sulfide itself can behave as either a nucleophilic reagent or a radical reagent, whereas hydrosulfides or sulfides behave solely as nucleophilic reagents.

3.3.1. Hydrogen Sulfide as a Nucleophilic Reagent

Hydrogen sulfide reacts as a nucleophilic reagent in the presence of acidic, basic, or metallic oxide catalysts.

Compounds such as alcohols or olefins react with hydrogen sulfide to form thiols (RSH). Thiols (with the exception of tertiary thiols) react like hydrogen sulfide to give the corresponding organic sulfides (RSR).

Substitution Reactions. Because of its widespread industrial applications, the best known substitution reaction is *sulfhydrolysis* (*thiolation*) *of alcohols*. This reaction occurs catalytically in the gas phase at ca. 300 °C. Thiols were first obtained by reacting hydrogen sulfide with alcohols on thorin or on pumice impregnated with thorin [73]. Subsequently, more selective, more active catalysts were developed based on activated alumina containing promoters such as soda or potash [74], metallic oxides, alkaline salts of transition-metal oxo acids [75], and heteropolyacids or their alkaline salts [76].

Primary alcohols are converted very efficiently into the corresponding thiols:

$$H_2S + ROH \longrightarrow RSH + H_2O$$

However, with secondary and especially tertiary alcohols, dehydration reactions are more prevalent.

Under catalytic reaction conditions similar to those used for alcohols, hydrogen sulfide reacts with aliphatic ethers to produce thiols. Cyclic ethers are converted to the corresponding sulfides by catalysis in the gas phase. For example, reaction of hydrogen sulfide with tetrahydrofuran yields tetrahydrothiophene [*110-01-0*] [77]:

A similar reaction with furan gives thiophene [*110-02-1*] [78]:

Hydrogen sulfide reacts with acetic anhydride in the presence of basic resins to form thioacetic acid [*507-09-5*] [79]:

$$H_2S + CH_3COOCOCH_3 \longrightarrow CH_3COSH + CH_3COOH$$

Addition Reactions. Catalytic addition of hydrogen sulfide to *olefins* follows Markovnikov's rule (i.e., the sulfhydryl group adds preferentially to the more highly substituted carbon of the double bond).

Linear olefins react with hydrogen sulfide in the presence of acid catalysts (e.g., acid zeolites, cation-exchange resins, alumina – silicas) to yield secondary thiols [80]. With branched olefins and acidic catalysts such as aluminum chloride, alumina – silica [81], zeolites [82], or cation-exchange resins [83], tertiary thiols are formed. Ethylene and cyclohexene are converted into thiols on metal oxide catalysts [84].

Hydrogen sulfide adds to the double bond of *acrylic derivatives* (nitrile, acids, esters) in the presence of basic catalysts such as amines [85], anion-exchange resins [86], or magnesium oxide [86].

Nucleophilic addition of the thiol function occurs at the carbon in the β-position with respect to the substituent group:

$$H_2S + CH_2{=}CHX \longrightarrow HSCH_2CH_2X$$
$$X = -CN,\ -COOH,\ -COOR$$

Base-catalyzed cleavage of *epoxides* with hydrogen sulfide gives mercaptoalcohols (hydroxythiols):

Basic catalysts may be mineral bases, amines, quaternary ammonium salts [87], anion-exchange resins [88], zeolites [89], or guanidines [90].

With ethylene oxide, the main product is mercaptoethanol [*60-24-2*]. Thiodiglycol or bis(2-hydroxyethyl) sulfide [*111-48-8*] is obtained as byproduct. The reaction can be catalyzed by thiodiglycol without a base [91].

The addition of hydrogen sulfide to *nitriles* is catalyzed by bases such as amines and gives thioamides:

An industrially important example of this reaction is the addition of hydrogen sulfide to cyanamide to form thiourea [*62-56-6*]:

With *aldehydes and ketones,* hydrogen sulfide yields dithiols or cyclic products, depending on conditions [92]:

Thus, with formaldehyde, methanedithiol ($HSCH_2SH$) [*74-93-1*] is obtained [93]. Acetone reacts with sulfur and hydrogen sulfide in an ammoniacal medium to form a cyclic polysulfide [*4475-72-3*] [94]:

3.3.2. Hydrogen Sulfide as a Radical Reagent

Hydrogen sulfide can react as a free radical:

$$HS{-}H \longrightarrow HS\cdot + H\cdot$$

Generation of these two species by thermal dissociation is difficult. Use of chemical initiators or exposure to UV light is much more efficient.

Radical addition of hydrogen sulfide to olefins yields thiols. In practice, the reaction can be initiated as follows:

1) *Chemical initiators* can be used at temperatures corresponding to their thermal decomposition. Azo derivatives, in particular azobisisobutyronitrile, have been used [95] with

or without catalyst promoters such as organic phosphines and phosphites [96].

2) *Ultraviolet radiation* can be employed. Reaction proceeds either by direct photolysis ($\lambda = 253.7$ nm), or via intermediate radical initiators ($\lambda = 300-400$ nm). The initiators are either chemical initiators that are decomposed at a lower temperature by photons (e.g., azo derivatives [97], phosphites [98], acetophenone derivatives [99]) or aromatic carbonyl derivatives such as benzophenone [100] or thioxanthone [101], preferably associated with organic phosphites [100, 101].

Addition proceeds by a free-radical chain mechanism and is of the anti-Markovnikov type, i.e., the HS · radical adds to the least substituted carbon of the double bond.

With a terminal olefin, the corresponding primary thiol is selectively formed. However, the thiol may decompose into a thiyl radical that can also add to the olefin to give the corresponding organic sulfide. The percentage of sulfide formed can be minimized by using an excess of hydrogen sulfide.

Photochemical addition of hydrogen sulfide is also possible with olefins containing functional groups (e.g., allyl chloride, acrylic acid, and acrylates).

3.3.3. Reaction of Hydrogen Sulfide in the Form of Hydrosulfide

For certain ionic reactions, hydrogen sulfide must be supplied in the form of alkaline hydrosulfides, or ammonium hydrosulfide in an aqueous or aqueous – alcoholic solution.

Nucleophilic Substitution. Nucleophilic substitution of halogen compounds is facilitated if the halogen is activated by its electronic environment. Thus, nucleophilic substitution cannot be used to obtain thiol compounds from chlorinated hydrocarbons. However, if the chlorine is activated by an α, β, or γ heteroatom (O, Si, S), or by an electron-attracting group (C=O, C=N), substitution proceeds easily, often with total conversion of chlorine and excellent selectivity [102]:

$$2\,NaSH + Cl-(CH_2)_n-COOH \longrightarrow HS(CH_2)_n-COONa + H_2S + NaCl$$
$$\downarrow +HCl$$
$$HS(CH_2)_n-COOH + NaCl$$

This method is used to synthesize thioglycolic acid [*68-11-1*] and mercaptopropionic acid [*107-96-0*].

Other mercaptans are obtained by similar techniques [103, 104]:

$$NaSH + ClCH_2CH_2OR \longrightarrow HSCH_2CH_2OR + NaCl$$
$$NaSH + Cl(CH_2)_3Si(OCH_3)_3 \longrightarrow HS(CH_2)_3Si(OCH_3)_3 + NaCl$$
$$NaSH + C_6H_5CH_2Cl \longrightarrow C_6H_5CH_2SH + NaCl$$

Acid chlorides react particularly well with alkaline hydrosulfides [105]. For example, thiobenzoic acid [*98-91-9*] is synthesized by reaction of benzoyl chloride with sodium hydrosulfide:

Some active esters may be subjected to sulfhydrolysis with hydrosulfides to form the corresponding thiols [106, 107]:

$$HSCH_2CH_2OCOCH_3 \xrightarrow[NH_3]{H_2S} HSCH_2CH_2SH + CH_3COOH$$

$$NH_2CH_2CH_2OSO_3Na \xrightarrow{NaSH} HSCH_2CH_2NH_2$$

Nucleophilic Addition. In an aqueous – alcoholic medium and in the presence of carbon disulfide, sodium hydrosulfide can react selectively with activated olefins to give thiols. Methyl mercaptopropionate [*2935-90-2*] has been prepared by this technique [108]:

$$NaSH + CH_2=CHCOOCH_3 \xrightarrow[\text{alcohol}]{CS_2} HSCH_2CH_2COOCH_3$$

4. Production

Hydrogen sulfide can be produced by (1) chemical reaction of sulfur with hydrogen or a hydrocarbon, or (2) hydrogen reduction or acid decomposition of a sulfide. It can also be recovered from natural gas, associated gases, and refinery gases.

4.1. Production by Chemical Reaction

Reaction of Sulfur with Hydrogen. Hydrogen sulfide is formed when hydrogen is fed into sulfur at 350 °C with or without a catalyst (e.g., bauxite, aluminum silicate, cobalt molybdate) [109, 110]. High pressure also aids the reaction.

$$H_2 + 1/2\,S_2 \rightleftharpoons H_2S$$

In the laboratory, hydrogen is fed into molten sulfur. Reaction occurs in a tube filled with pumice [111–113]. In the industrial production of hydrogen sulfide (Fig. 1), the reaction occurs at 450 °C and 0.7 MPa. Hydrogen sulfide is separated from sulfur vapor by cooling and solidifying the sulfur on the walls of a heat exchanger. The exchanger is alternately cooled and heated to remelt and eliminate the sulfur deposit. Operating data for a typical plant follow [114]:

Production capacity:	1 – 60 t/d
Consumption (per metric tonne of hydrogen sulfide produced):	
Hydrogen (purity 98 %)	67 kg
Sulfur (purity 99 %)	1066 kg
Electrical power	266 kW · h
Typical analysis of product	95 vol % H_2S, 3 vol % H_2, 2 vol % impurities

Reaction of Sulfur with Hydrocarbons. Sulfur reacts with methane to form a mixture of hydrogen sulfide and carbon disulfide. Carbon disulfide can be hydrolyzed, giving additional hydrogen sulfide [110], [115, 116]. With higher alkanes ($>C_{10}$) having a low vapor pressure, reaction takes place at 200 – 300 °C [115, 117]. Examples of laboratory preparation are given in [118, 119].

Reduction of Sulfides. Hydrogen sulfide is formed by reduction of sulfides (e.g., FeS_2, CuS) with hydrogen at > 500 °C.

Reaction of Sulfides with Dilute Acid. The most convenient method of preparing hydrogen

Figure 1. Industrial production of hydrogen sulfide from hydrogen and sulfur
a) Sulfur makeup pump; b) Sulfur cooler; c) Sulfur recycle pump; d) Reactor; e) Electric heater; f) Quench tower; g) Gas cooler

sulfide in the laboratory is to react sodium sulfide with dilute hydrochloric [120, 121] or sulfuric [122] acid. Other sulfides (CaS, ZnS, FeS, Sb_2S_3) can also be used. The purest hydrogen sulfide is obtained from Sb_2S_3.

4.2. Recovery from Gas (→ Gas Production, Chap. 5.4.2.; → Gas Production, Chap. 5.4.3.; → Natural Gas)

Natural gas or gas associated with crude oil is sour, i.e., it contains varying quantities of hydrogen sulfide, from traces to 70 – 80 vol %. This hydrogen sulfide is nearly always associated with varying quantities of carbon dioxide. Refinery gases produced in hydrodesulfurization or cracking units have a very high ratio of hydrogen sulfide to carbon dioxide. When the hydrogen sulfide level of the gas reaches a certain limit, partial or total sweetening (i.e., removal of hydrogen sulfide) is necessary to comply with transportation, distribution, and antipollution requirements. Sweetening gives an acid gas mixture of hydrogen sulfide and carbon dioxide that is generally used for sulfur recovery by the Claus process (→ Sulfur) but also serves as a source of hydrogen sulfide. Hydrogen sulfide is obtained from the gas

1) directly if the hydrogen sulfide – carbon dioxide ratio is high enough to give an acid gas with the desired hydrogen sulfide content (80 – 90 vol %) or if a selective sweetening process is used;
2) after additional treatment, consisting of selective reprocessing (desired purity, 90 – 95 %) or compression and subsequent distillation (minimum purity 99.5 %).

Absorption. Hydrogen sulfide can be recovered from gas containing sufficiently high quantities of it by (selectively) sweetening the gas with respect to carbon dioxide by chemical or physical absorption [123–126].

Absorption by a chemical solvent (amines or potassium carbonate) is a function of pressure and temperature. Absorption by a physical solvent is primarily a function of pressure.

Industrial absorption processes for gas sweetening are summarized in Table 5.

Table 5. Industrial absorption processes for hydrogen sulfide recovery from gases

Solvent	Trade name	Lincensing company
Chemical absorption with aqueous solutions		
N-Methyldiethanolamine (5 N solution)	Ucarsol-MDEA	Union Carbide
Diethanolamine (4 N solution)	SNPA-DEA	Elf Aquitaine
Diisopropanolamine (2 N solution)	ADIP	Shell
N-Methyldiethanolamine (4 N solution)	MDEA	Elf Aquitaine
Diglycolamine (6 N solution)	Econamine	Fluor
Hindered amine solution	Flexsorb	Exxon
Chemical absorption with alkaline salt solutions		
K_2CO_3, catalyst (amine borates)	Catacarb	Eickmeyer
K_2CO_3, catalyst (diethanolamine)	Benfield	Union Carbide
K_2CO_3, catalyst (arsenic salts)	Giammarco-Vetrocoke	Giammarco
Methylaminopropionate	Alkacid-M	BASF
Dimethylaminoacetate	Alkacid-DIK	BASF
Physical absorption		
Anhydrous propylene carbonate	Fluor	Fluor
Dimethyl ether of poly(ethylene glycol)	Selexol	Norton
Cold methanol	Rectisol	Lurgi
N-Methylpyrrolidone	Purisol	Lurgi
Aqueous solution of diisopropanolamine (D) or methyldiethanol-amine (M), sulfolane	Sulfinol D (or M)	Shell
Mixture of monoethanolamine or diethanolamine and methanol	Amisol	Lurgi
Methyl isopropyl ethers of poly(ethylene glycol)	Sepasolv	BASF

Figures 2 and 3 show typical process schemes for absorption with a chemical and a physical solvent, respectively. The sour gas is washed in a countercurrent absorber. The rich solvent is regenerated by flashing and stripping. Flashing (physical solvent) and reboiling (chemical solvent) are the main regeneration factors.

The production process used depends on the characteristics of the gas to be treated and the desired hydrogen sulfide specifications.

If maximum selectivity with regard to hydrogen sulfide is required, a process based on absorption with a selective amine is chosen (a tertiary alkanolamine such as *N*-methyldiethanolamine, MDEA) [127].

Hydrogen sulfide reacts readily and directly with tertiary amines. Carbon dioxide, however, can only react with tertiary amines indirectly in the form of carbonic acid to produce amine carbonates. Carbonic acid first has to be formed by

Figure 2. Recovery of hydrogen sulfide with a chemical solvent

reaction of carbon dioxide with water and this step is much slower than direct reaction. An important principle of selective absorption is therefore the selection of a gas – liquid contact time that is long enough to eliminate hydrogen sulfide, but short enough to minimize the coabsorption of carbon dioxide.

If the partial pressure of hydrogen sulfide in the sour gas is sufficiently high (≥ 0.3 MPa) and significant quantities of hydrocarbons (a few percent) can be tolerated, a physical solvent process may also be chosen.

Distillation. The industrial distillation of an acid gas in which the purity of hydrogen sulfide is insufficient was developed by Elf Aquitaine at its Lacq plant [128]. Hydrogen sulfide is obtained either as a liquid or as a gas with a purity > 99.5 %. The acid gas is first treated with activated carbon to eliminate heavy hydrocarbons and dried with a solid adsorbent (alumina, silica beads, or molecular sieves). It is then compressed to 2.5 – 3.5 MPa and distilled in a tray column or packed column. Liquid hydrogen sulfide is obtained at the bottom of the column and easily vaporized for more convenient distribution.

If the acid gas has a very low hydrogen sulfide content ($H_2S/CO_2 < 0.2$), separation of hydrogen sulfide and carbon dioxide can be improved by introducing a C_3– C_6 alkane above the column feed [129]. The hydrogen sulfide obtained is slightly less pure.

5. Environmental Protection

Hydrogen sulfide is not only produced industrially, it also originates from natural sources (see also Chap. 1):

1) diffusion into underground water from oil and natural gas wells,
2) formation in lakes by aerobic bacterial fermentation,
3) production during biological wastewater treatment, and
4) formation as a degradation product in the agricultural food industry, slaughterhouses, and the paper industry.

In the environment, the toxicity of hydrogen sulfide is due to the hydrogen sulfide molecule itself rather than to hydrosulfide or sulfur ions. For example, bacterial metabolism is inhibited when the hydrogen sulfide content of the surroundings reaches 70 – 200 mg/L [130]. Because hydrogen sulfide does not accumulate in living organisms, it cannot contaminate the food chain [131]. Natural elimination of hydrogen sulfide occurs mainly by diffusion into the atmosphere, but it is also subjected to biological or chemical degradation to form sulfur oxides and sulfur. In water, hydrogen sulfide is converted into elemental sulfur or insoluble heavy-metal sulfides.

Accidental leaks of hydrogen sulfide gas can be absorbed directly with aqueous solutions of sodium carbonate, sodium hydroxide, sodium hypochlorite, or iron(III) chloride. When liquid hydrogen sulfide is spilled on the ground, adsorbents such as activated carbon should be used to prevent the spread of liquid and reduce the emission of vapor [132]. Water polluted with hydrogen sulfide can be stripped and neutralized with lime, sodium carbonate, or sodium bicarbonate. Sulfur ions are then eliminated by precipitation.

Industrial effluents containing hydrogen sulfide must be treated or incinerated if their hydrogen sulfide content exceeds 0.001 vol %. The final procedure depends on the sulfur content and local discharge regulations. For example, for residual gases in sulfur plants, treatment can consist of

1) hydrogenation of residual sulfur compounds, followed by washing with amines that selectively absorb hydrogen sulfide and recycling of the effluent from the amine regenerator to the inlet of the sulfur plant: Scot (Shell), Elfapur (Elf Aquitaine) processes;
2) incorporation of an additional treatment stage based on the catalytic Claus reaction at low temperature (135 –150 °C). The sulfur obtained remains trapped in the catalyst and must be desorbed during a subsequent regeneration cycle: Sulfreen process (Elf Aquitaine, Lurgi).

When the sulfur concentration is not too high, washing the residual gas with chemically regenerable substances (as used in the LO-CAT process) or with nonregenerable substances (e.g., sodium hypochlorite or sodium hydroxide) may be more economical. Alternatively, the gases may be treated by conventional adsorption (activated carbon, metal oxides) or by adsorption

combined with biological regeneration [133]. The latter involves immobilizing bacteria on an adsorbent to incite autopurification.

6. Analysis

There is no universal method of analysis for the determination of hydrogen sulfide. Each method depends not only on the medium in which the quantity of hydrogen sulfide is to be determined (gaseous mixtures, liquid effluents) and on the concentration of hydrogen sulfide in the medium, but also on the nature of the desired results.

The following examples are by no means exhaustive:

1) Determination in a sour gas by iodometry [134], gas-liquid chromatography [135], and argentimetry [136].
2) Determination in a commercial purified gas by iodometry [137], polarography [138].
3) Determination in a fuel gas with lead acetate [139].
4) Determination in the atmosphere [140].

7. Storage, Handling, and Transportation

7.1. Storage and Handling

The most important problem in storing hydrogen sulfide is the material used for the storage vessel.

Anhydrous hydrogen sulfide does not react with steel at ambient temperature. However, in an aqueous medium, it attacks iron to form iron sulfide and hydrogen. The hydrogen can diffuse into the metal where it is trapped in cavities, causing blistering and embrittlement. The degree of corrosion depends on the grade of steel and is very limited with stainless steel. Ferritic steels are much more sensitive to hydrogen embrittlement than austenitic steels. Embrittlement can be important with highly resistant steel. High-strength steel exposed to hydrogen sulfide is likely to crack under stress. Stress-relieving treatment after welding reduces residual stresses. Thus, the steel used for hydrogen sulfide storage vessels and pipes must be chosen carefully.

Because of the problems associated with transportation of hydrogen sulfide and its toxicity, storage capacities are restricted; the product must be used close to its production site whenever possible. Nevertheless, hydrogen sulfide is transported by pipeline over several kilometers in Europe and the United States. Liquid hydrogen sulfide is also transported in specially designed containers. Particular attention should be given to emptying devices (valves) and their protection during transportation.

Storage tanks for liquid hydrogen sulfide should be equipped with a safety device system as shown in Figure 4. The blowdown tank is a reserve storage capacity that enables rapid emptying of liquid hydrogen sulfide in case of accident. It can be operated by an "emergency stop"

Figure 4. Storage tank for liquid hydrogen sulfide equipped with safety devices
a) Storage tank; b) Safety valve; c) Relief valve; d) Blowdown tank; e) Block valve

switch that automatically actuates the safety valves. The gas phase in the storage tank is connected directly to a flare by means of a relief valve that can be bypassed via a safety valve.

7.2. Transportation

Transportation of liquid hydrogen sulfide by air (IATA) is strictly prohibited. Transportation in bulk containers by sea is also prohibited (IMDG). Small containers of < 1 t or small bottles are generally used for road and rail transportation. The transport of hydrogen sulfide in Europe by rail has been abandoned; it is used instead at the site of production. In the United States, liquid hydrogen sulfide is transported in specially designed tankers. Hazard classifications for hydrogen sulfide are as follows:

IMDG Code, class 2.1, label 2.1 + 6
RID/ADR, class 2, label 3 + 6.1
United States, CFR 49 : 172.02, flammable
UN no. 1053

The sulfur content of crude oil can result in the production of hydrogen sulfide, representing a risk for field personnel and for the transporter. In sea transport, maintenance of storage tanks under a blanket of inert gas does not eliminate the risk of explosion. The risk of sulfur formation in the tankers should also be kept in mind. Wearing gas masks in the pump room of tankers is compulsory when the hydrogen sulfide content exceeds 10 ppm. The same measures should be taken for personnel connecting up the loading arms.

8. Uses

Production of Sulfur. Natural gas containing hydrogen sulfide is currently one of the most important sources of elemental sulfur. For commercial use, sour natural gas must first be sweetened to remove the acid compounds, mainly hydrogen sulfide and carbon dioxide. The resulting acid gas is used for the production of sulfur by the Claus process [141, 142]:

$$2\,H_2S + SO_2 \longrightarrow 3/n\,S_n + 2\,H_2O$$

For further details, see → Sulfur. Sulfur is marketed in liquid or solid form. In the liquid state, itmust first be degassed to remove all traces of hydrogen sulfide. The sales specification of sulfur in Europe requires a hydrogen sulfide content of < 10 ppm. This value is obtained by degassing liquid sulfur into sulfur pits with ammonia before dispatch.

Production of Metal Sulfides. The reaction of hydrogen sulfide with soda or lime solutions results in formation of the corresponding sulfides. Sodium sulfide is generally marketed in a solid hydrated form. Acid sulfides or hydrosulfides [e.g., NaSH or $Ca(SH)_2$] are marketed either as crystals or as concentrated aqueous solutions.

Sodium sulfide is used as a lignin demethylation agent in the Kraft process for manufacturing paper pulp. Mixtures of sodium and calcium sulfides are powerful reducing agents of disulfide bonds. They attack the cystine molecules of keratin and are used in the leather industry for chemical depilation of animal hides (→ Leather).

Flotation. Preliminary treatment with hydrogen sulfide is sometimes required for the purification of ore by selective flotation. Certain mineral species in the ore are sulfurized, which considerably increases the selectivity of flotation collectors and facilitates separation of valuable metallic species. This process is used in the purification of nickel and manganese.

Catalyst Activation and Poisoning. Certain catalysts reach their maximum activity only when their constituent metals are in the form of sulfides (e.g., the hydrotreating catalysts used in oil refining). Preliminary treatment with hydrogen sulfide is sometimes necessary.

However, hydrogen sulfide also poisons some hydrogenation and reforming catalysts with a platinum or palladium base. This can be used to advantage to reduce initial catalyst activity and limit coking (i.e., formation of carbonaceous deposits). Gasoline reforming catalysts, for example, are always selectively poisoned with a small quantity of hydrogen sulfide prior to use.

Treatment of Metallic Surfaces. Superficial sulfurization of metals with hydrogen sulfide allows modification of their physical or chemical properties. Hydrogen sulfide is used

for passivation of the walls of reactors operating at high temperature in petrochemical operations such as steam cracking and hydrodealkylation. This treatment prevents desirable secondary reactions.

Another use of hydrogen sulfide is the formation of a layer of sulfide on the surface of steel wires or plates that are to be coated with paint or plastic. This treatment protects the coating or improves the action of adhesive primers.

Analytical Chemistry. Hydrogen sulfide has long been used to selectively precipitate group 1, 2, and 3 metal cations. The metals are qualitatively identified by the color of the sulfides formed.

Production of Thioorganic Compounds. The most common industrial application of hydrogen sulfide is the production of organic compounds with a thiol function (i.e., RSH, where R is a hydrocarbon group) or a thiol group and another function (e.g., alcohol, acid).

Table 6 shows the most important thioorganic compounds (in terms of tonnage) produced from hydrogen sulfide in the United States and Europe. Other important thioorganic compounds derived from hydrogen sulfide are tetrahydrothiophene and mixtures of thiols or sulfides (often containing *tert*-butanethiol or diethylsulfide). These are used as strong-smelling additives for gas odorization.

Long-chain thiols also represent a range of useful products, especially *n*-dodecanethiol and *n*-octanethiol. These are used as intermediates in the synthesis of plant protection agents and as polymerization agents.

9. Economic Aspects

Total world sulfur production was 56.6×10^6 t in 1986, compared with 51.7×10^6 t in 1977. Sulfur recovered from the treatment of sour gas (i.e., from hydrogen sulfide) accounts for 25 % of this (ca. 14×10^6 t in 1986, 11.8×10^6 t in 1977).

The primary producing countries are listed below, with their 1986 production figures in 10^6 metric tonnes per year:

Western Canada	5.2
United States	2.2
former Soviet Union	1.8
Saudi Arabia	1.2
Federal Republic of Germany	1.0
France	0.9

Recovery of sulfur from hydrogen sulfide will continue to expand worldwide. The former Soviet Union is expected to become the main producer of sulfur from sour gas due to development of the Astrakhan gas field (hydrogen sulfide content: 26 %). Astrakhan I started producing early in 1987 and Astrakhan II is due to be put on stream early in 1989.

Canada should continue to be a major producer because of the development of the Caroline gas field in Alberta. The Middle East is also expected to play a major role, with substantial tonnage from Iran and Qatar. Production in

Table 6. Thioorganic compounds produced from hydrogen sulfide

Product	Formula	Raw materials	Annual world production, t	Producers	Uses
Methanethiol (methyl mercaptan) [*74-93-1*]	CH_3SH	methanol + H_2S	70 000	Pennwalt Rhone Poulenc Elf Aquitaine	base product for manufacture of methionine, dimethyl disulfide, and plant protection products
Thioglycolic acid (mercapto acetic acid) [*68-11-1*]	$HSCH_2COOH$	chloroacetic acid + NaSH	15 000	Elf Aquitaine Bock Merck	manufacture of esters, poly(vinyl chloride) stabilizers, and cosmetics
tert-Dodecanethiol [*25103-58-6*]	$C_{12}H_{25}SH$ (mercaptan mixture)	tetrapropylene or triisobutylene + H_2S	13 000	Pennwalt Phillips Elf Aquitaine Bayer	chain-transfer agent in radical polymerization; manufacture of polysulfides
Ethanethiol (ethyl mercaptan) [*75-08-1*]	CH_3CH_2SH	ethylene + H_2S	12 000	Phillips Pennwalt Elf Aquitaine	manufacture of plant protection products
Mercaptoethanol [*60-24-2*]	$HSCH_2CH_2OH$	ethylene oxide + H_2S	8000	Phillips Morton Thiokol Alcolac BASF Elf Aquitaine	soluble chain-transfer agent for polymerization in aqueous media; manufacture of plant protection products; poly(vinyl chloride) stabilizers

the United States and the Federal Republic of Germany is likely to stabilize at $(2.3-2.5)\times10^6$ and 1.0×10^6 t, respectively. In France, production will decline gradually due to depletion of the Lacq gas field (hydrogen sulfide content: 15 %). Sulfur recovered from hydrogen sulfide has been the major source of accumulated stocks, which are used to swing production to balance the market when needed. At the end of 1987, the stock of sulfur from sour gas, in tonnes, was

Western Canada	6.7×10^6
France	2.2×10^6
Saudi Arabia	1.5×10^6

10. Toxicology

Hydrogen sulfide is a toxic gas. Human poisoning is related to its acute toxicity. Chronic toxicity has not been demonstrated in people exposed to concentrations lower than those that induce acute or subacute poisoning [143, 144].

Animal Data. Much toxicological data has been published on animals exposed to massive dosages of hydrogen sulfide. These data confirm observations made on humans, but information on chronic or long-term effects remains limited. The acute toxicity of hydrogen sulfide is comparable in animals and humans.

Chronic toxicity studies have been carried out on rabbits, rats, and mice that inhaled daily doses of hydrogen sulfide at concentrations in air up to 80 ppm over three to five consecutive months [143–145]. Despite numerous detailed examinations, including neurological tests, no specific chronic effects were found. Mutagenicity testing has shown a lack of genotoxic effects on bacteria in vitro [146] and on rats in vivo [147].

Metabolism. Lack of a chronic toxic effect of hydrogen sulfide in animals and most probably in humans may be explained by the fact that it does not build up in the body. Hydrogen sulfide is metabolized rapidly, mainly into less toxic, oxidized metabolites that are quickly eliminated via the kidneys.

Hydrogen sulfide is readily absorbed by the pulmonary tract, which at the same time represents an excretory pathway for untransformed hydrogen sulfide. Hydrogen sulfide that is not eliminated by the respiratory tract binds to circulating proteins in the blood and is distributed rapidly to all tissues, including the nervous system. It is subsequently metabolized and detoxified as shown in Figure 5 [144].

Hydrogen sulfide is detoxified by oxidation to sulfate (the primary reaction) or by methylation (not yet confirmed). The toxicity of hydrogen sulfide is due to its reaction with protein constituents of essential enzymes or metalloproteins, especially the iron-containing metalloproteins of the respiratory cell chain.

During chronic exposure, the amount of hydrogen sulfide entering the organism is so small that it is neutralized by the above detoxification reactions. However, during massive acute exposure, the detoxification capacity is exceeded; the reaction of hydrogen sulfide with proteins can thus lead to poisoning.

Human Risk and Pathology. The acute toxic risk of hydrogen sulfide and the pathology observed in human poisoning are summarized in Tables 7 and 8 (see next pages) [148, 149].

11. Occupational Health and Safety

The main safety precautions listed here result from thirty years' experience at Lacq [150] and from the literature. Hydrogen sulfide has several properties that make it a highly dangerous gas:

1) high toxicity;
2) flammability: it ignites spontaneously at 260 °C (compared to 537 °C for methane) and forms an explosive mixture with air when the hydrogen sulfide content is 4 – 44 vol % (compared to 5 – 15 % for methane) [151];
3) density: being heavier than air, it accumulates in low-lying areas of installations;
4) ability to embrittle steel (Section 7.1); and
5) insidiousness: persons intoxicated with hydrogen sulfide no longer discern its characteristic smell of rotten eggs before the dangerous threshold concentration (50 – 100 ppm) is reached.

General Precautions. Areas in which hydrogen sulfide is produced, utilized, and stored must be isolated and delimited.

Figure 5. Metabolism of hydrogen sulfide in humans and animals
Abbreviations: GSH, reduced glutathione; GSSG, glutathione; $NADP^+$, oxidized nicotinamide – adenine dinucleotide phosphate; NADPH, reduced nicotinamide – adenine dinucleotide phosphate

Table 7. Acute toxic effects of hydrogen sulfide in humans

Concentration	Duration of exposure				
of H_2S, ppm	15 min	15 min – 1 h	1 – 4 h	4 – 8 h	Comments
10				eye irritation	maximum tolerable concentration for prolonged exposure
50 – 100	loss of olfactory perception	eye irritation	eye and bronchial irritation	danger in case of continuous exposure	working conditions necessitate protective measures
150 – 250	loss of olfactory perception	eye and bronchial irritation	serious respiratory distress and asthenia		working conditions necessitate protective measures
300 – 400	loss of olfactory perception, eye and bronchial irritation, asthenia	severe respiratory distress, acute asthenia	pulmonary edema and risk of death		risk of death if no appropriate measures taken
500 – 1000	loss of consciousness, respiratory distress	risk of pulmonary edema and death			risk of death if no appropriate measures taken
>1000	immediate loss of consciousness and respiratory distress				risk of death if no appropriate measures taken

Table 8. Human pathology in hydrogen sulfide poisoning

	Degree of poisoning		
	Weak	Intermediate	Severe
Early signs	equilibrium problems	warning signs of short duration	immediate coma
Immediate effects	loss of consciousness for a few seconds; rapid regain of consciousness	sudden loss of consciousness lasting a few minutes, followed by headache, respiratory distress, gastric pain, diarrhea (following day)	prolonged deep coma with cyanosis, respiratory distress, occasionally cardiac distress; regain of consciousness is difficult and agitated
Long-term effects	recovery	recovery or bronchial fragility; asthenia	bronchopulmonary sequelae
Emergency treatment	evacuation from danger area; administration of oxygen	evacuation from danger area; administration of oxygen; respiratory assistance if needed; intravenous vitamin C; medical observation for several hours	evacuation from danger area; administration of oxygen; respiratory assistance if needed; intravenous vitamin C; cardiotonics and neurosedatives if needed; hospitalization

Only authorized personnel should have access to these areas, i.e., personnel having undergone medical tests to detect ocular, respiratory, or cardiovascular disease, and signs of alcoholism. All authorized personnel should undergo special training to deal with the inherent risks of working in a hydrogen sulfide environment. They should be equipped with gas masks and undergo regular training in their use.

The usual precautions should be taken in all areas where an explosive atmosphere is likely to be found (sources of flame, electric equipment, ect.). "No smoking" signs should be displayed and strictly observed.

Only piping, apparatus, and containers made from special steel or alloys should be used; the grade should be suitable for the conditions of use. The use of copper and its alloys should be prohibited.

Storage and Transportation (see also Chap. 7). The storage area should be well ventilated and, if possible, equipped with a water cooling system in case of fire.

Hydrogen sulfide containers should be stored separately from incompatible products (oxidizing agents, inflammable products, powerful acids, etc.) and away from direct sunlight. A special parking area should be provided for vehicles transporting hydrogen sulfide.

Each container should carry a label indicating that the contents are highly flammable and toxic. The label should also list the special risks and include cautionary advice.

- Modified EEC directive 67/548
- EEC No. 016-001-00-4
- *Danger symbols:* highly flammable and toxic
- *Nature of special risks attaching to dangerous substances:*
- R.13 Extremely flammable liquefied gas
- R.26 Very toxic by inhalation
- *Safety advice concercing dangerous chemical substances:*
- S7/9 Keep container tightly closed in a well-ventilated place
- S.25 Avoid contact with eyes
- S.45 In case of accident or clinical symptoms medical advice should be sought immediately.

Installation and Handling. Apparatus should be properly closed and tightly sealed. Waste gas from discharge and pressure valves should be sent to a flare to avoid emission of hydrogen sulfide into the atmosphere. This flare can burn off hydrogen sulfide in dangerous situations, eliminate air from the discharge piping before discharge, and purge hydrogen sulfide after discharge.

Emissions produced under normal conditions should be recovered at source, and low-lying areas should be ventilated thoroughly.

Personnel working on apparatus containing (or having contained) hydrogen sulfide should be equipped with insulated gas masks and wear protective clothing, goggles, and long gloves. No one should be allowed to work alone in a zone where hydrogen sulfide is handled.

Frequent checks of the atmosphere should be made. Hydrogen sulfide detection devices should be installed (see below); smell should not be relied on for detection.

Programmed preventive maintenance should be carried out in all hydrogen sulfide installations, particularly on sealing devices. A fire per-

mit should be obtained to use tools producing flame, heat, or sparks.

Pyrophoric sulfides should be kept constantly humid. They should be extracted and incinerated as soon as possible. After maintenance work, all traces of humidity should be eliminated.

Emergency Measures. A plan should be drawn up for evacuation of personnel if the concentration of hydrogen sulfide exceeds the norm. Gas masks must be put on as soon as an alarm is given. Appropriate measures to be taken in the case of leakage, fire, or accident should be displayed prominently in the installation.

In the event of leakage without fire, the leak should be isolated and sprayed with water. Uncontrollable gas should be sent to a flare pit, and all sources of heat should be removed or shut down.

If the leaking material has caught fire, the fire should be put out only when it presents an especially serious threat to the environment or when the leak can be rapidly controlled.

In the event of accidental gassing, lifesaving intervention should be undertaken only after the rescuer has donned an insulating gas mask. The victim should be removed rapidly from the danger zone and should receive necessary first aid and medical treatment as soon as possible.

Detection of Hydrogen Sulfide in Air. Permanent detection devices are necessary both in and around the hydrogen sulfide storage area. They should set off both audible and visual alarms as soon as the concentration of hydrogen sulfide in air exceeds 10 ppm. Several models are available. An *electrochemical sensor* functions on the gas diffusion principle: hydrogen sulfide in air reacts chemically with an electrolyte (Sulfytron 4010, Draeger, FRG). In a *semiconductor* detector, air containing hydrogen sulfide diffuses into the specially adapted semiconductor and modifies its electrical resistance (General Monitors, United States).

Portable detectors can be used for random measurement of hydrogen sulfide concentration. An electrically or manually operated pump sucks air through a reactive tube divided into zones that become colored on contact with the polluting gas (Draeger model 21/31 with specific tube for hydrogen sulfide).

A simple but effective method of detecting a leak is to use lead acetate paper. The paper becomes black in the presence of hydrogen sulfide but gives no indication of concentration.

Exposure Limit Values [152]. The average permitted concentration of hydrogen sulfide in air varies from country to country:

TLV (TWA) 5 – 10 ppm (vol)
TLV (STEL) 10 – 15 ppm

1. Hydrogenation

Catalytic hydrogenation refers to the addition of hydrogen to an organic molecule in the presence of a catalyst. If the molecule undergoes cleavage, the reaction is referred to as hydrogenolysis. These reactions are used to produce a variety of both bulk and fine organic chemicals. In addition, hydrogenation is often used in various purification processes (e.g., selective reduction of trace amounts of acetylene in an ethylene stream or traces of butadiene in a butene stream, and removal of unwanted oxygen, hydrogen, or carbon oxides from a variety of systems).

A large number of hydrogenation catalysts are now available, and the scope of hydrogenation has become very large. Most functional groups can be reduced readily, often under mild conditions, and frequently with high chemo-, regio-, and stereoselectivity. Monographs detailing the scope and use of hydrogenation have been written by AUGUSTINE [1], FREIFELDER [2], RYLANDER [3–5], and ZYMALKOWSKI [6].

Hydrogenation is an exothermic reaction and the equilibrium usually lies far toward the hydrogenated product under most operating temperatures:

$$A + n\,H_2 \rightleftharpoons B \qquad \Delta H < 0$$

As the temperature increases, the equilibrium shifts toward the left, and the reverse reaction, dehydrogenation, can itself be a useful synthetic process (see Chap. 2). Industrial hydrogenation requires a means of limiting the temperature increase arising from the exothermic reaction; a higher temperature usually has a favorable effect on reaction rate, but may affect selectivity and catalyst life adversely.

Hydrogenation is influenced by a number of factors, including catalyst, solvent, substrate purity, and operating conditions. Temperature, pressure, agitation, and catalyst loading can each influence both the rate and the selectivity of hydrogenation. In general, as temperature, pressure, agitation, and catalyst loading increase, the rate of hydrogenation increases until a limit is reached. The influence of operating variables on selectivity is less straightforward but can often be linked to the effect of these and other variables on hydrogen availability at the catalyst surface.

1.1. Hydrogen Availability and Mass Transport

Hydrogenation is carried out in both the liquid and the gas phases, but liquid-phase reactions are much more common. In liquid-phase systems, transport of hydrogen to the catalyst surface is frequently the rate-limiting step. To react with the substrate, hydrogen must move from the gas phase into the liquid and then to the solid catalyst and into its porous structure. This net movement of hydrogen to the catalyst is the result of concentration gradients, which develop when hydrogen is consumed by the catalytic reaction.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a13_487

The concentration of hydrogen at the catalyst surface can vary widely, depending on the ratio of the rate of hydrogen consumption to the rate of hydrogen supply [7].

This rate ratio can have an important influence on selectivity. It is, for instance, an important factor in controlling selective removal of multiple unsaturation and the extent of cis–trans isomerization during hydrogenation of natural oils to make edible products.

1.2. Catalysts

Hydrogenation catalysts are of two types, heterogeneous and homogeneous. *Heterogeneous catalysts* are solids that form a distinct phase in the gas or liquid environment. *Homogeneous* catalysts dissolve in the liquid medium, forming only a single phase; a well-known catalyst of this type is the Wilkinson catalyst, $(Ph_3P)_3RhCl$.

Homogeneous Catalysts. Homogeneous hydrogenation catalysts are used infrequently in industry. They are difficult to separate from the reaction media and are not employed if a suitable heterogeneous catalyst is available. Nonetheless, they are useful in a variety of hydrogenation processes that are not possible with heterogeneous catalysts [8], [9]. Expanded use of homogeneously catalyzed hydrogenation awaits only industrial demand for its products.

A noteworthy industrial use of a homogeneous catalyst is the asymmetric hydrogenation of an achiral olefinic precusor of L-Dopa (3,4-dihydroxyphenylalanine, used in the treatment of Parkinson's disease; see → Parkinsonism Treatment) over a complex rhodium catalyst carrying chiral ligands. Optical yields are nearly quantitative.

Heterogeneous Catalysts. Heterogeneous catalysts can be divided into two types: those used in *fixed-bed processing,* in which the catalyst is stationary and the reactants pass over it, and those used in *fluidized-bed* or *slurry processing.* The former have a relatively large particle size, 0.79 – 6.35 mm, in various forms. Slurry or fluidized-bed catalysts are fine powders that can be suspended readily in a liquid or gas.

Many *metals* and *metal oxides* have general hydrogenation activity, but marked differences exist among them. Nickel, copper, cobalt, chromium, zinc, iron, and the platinum group (platinum, palladium, rhodium, and ruthenium) are among the elements frequently found in commercial hydrogenation catalysts. Combinations of these or other elements are sometimes used to confer additional activity, selectivity, stability, or life.

Palladium, platinum, rhodium, and ruthenium make exceptionally active hydrogenation catalysts and are used frequently when equipment or stability limitations permit operation only under mild conditions. They can effectively reduce most functional groups. Nickel is used to reduce a variety of functional groups, usually under more vigorous conditions than the platinum group. Copper chromite is used mainly to reduce esters to alcohols. Cobalt or iron, in the presence of ammonia, is an effective catalyst for the reduction of nitriles to primary amines.

Catalyst Selectivity. In series reactions of the type $A \rightarrow B \rightarrow C$, both mechanistic and thermodynamic selectivity are involved in the formation of B. These selectivities can vary widely with the catalyst used. *Thermodynamic selectivity,* which is related to the relative free energies of adsorption of A and B, refers to the competition of A and B for catalyst sites. The tendency for B to occupy a catalyst site relative to A increases as B accumulates and as A is depleted. High thermodynamic selectivity demands that A be adsorbed much more strongly than B and that the rate of displacement of B by A be high relative to the rate of hydrogenation of B to C. Thermodynamic selectivity is affected by depletion of A in the vicinity of the catalyst because of intra- and interparticle diffusion resistance. *Mechanistic selectivity* refers to the extent to which C is formed from A without the formation of desorbed B; it is related to the relative rates of $A \rightarrow B$ and $A \rightarrow C$ in the equation $B \leftarrow A \rightarrow C$. Either thermodynamic or mechanistic selectivity may be more important, but both must be high if B is to be obtained in good yield.

1.3. Techniques

All hydrogenation reactors serve to bring hydrogen, catalyst, and substrate together in the absence of oxygen. Liquid-phase substrates may be hydrogenated neat or in the presence of a suitable *solvent*; use of a solvent is one of the best available means for markedly altering selectivity. Solvents also help to moderate the heat of reaction, aid in catalyst handling and recovery, and permit the reduction of solid substrates. A convenient solvent may be the product itself or the solvent used in a previous or subsequent step. Militating against the use of solvent is diminished space – time yield and the cost of solvent and of its removal.

1.3.1. Slurry Reactors

Hydrogenation is exothermic, and some means of removing the reaction heat must be provided to avoid excessive temperature. In liquid-phase slurry reactions, cooling is usually accomplished by coils within the reactor. The reaction mass can also be cooled by circulating the mixture over external cooling elements. The latter save reactor space and permit the reactor to be cleaned more easily.

Slurry reactors must be provided with some sort of agitation to aid in the rapid transport of hydrogen from the gas phase to the catalyst suspended in the liquid medium. Agitation also helps in the removal of heat, and agitators can be designed to favor either hydrogen transport or heat removal, as required. Externally cooled systems can be engineered to return the reaction slurry to the reactor by a venturi tube through which hydrogen is drawn into the passing stream. Such a system gives efficient mixing, and much of the hydrogenation is thought to take place within the nozzle itself. Alternatively, the slurry can be returned to the reactor through a shower-type arrangement in which substrate and catalyst particles are sprayed into hydrogen in the head space.

1.3.2. Trickle-Bed Reactors

Continuous hydrogenation is carried out commonly in trickle-bed reactors (columns packed with catalyst over which substrate and hydrogen pass concurrently downward). This type of reactor is used extensively in the petroleum industry for various reactions such as hydrocracking and hydrodesulfurization. The residence time distribution is close to that of plug flow, which permits high conversion in a single vessel. Operation is continuous, handling is minimal, and catalyst separation from product is trivial. Heat removal, however, is a major problem unless small-diameter tubes are used. At times, reactors are placed in series, with hydrogen injected between beds for temperature control. Beds are usually of uneven height, becoming longer as the reactant is depleted [10].

1.3.3. Bubble Column and Ebulliated Bed Reactors

Bubble columns resemble trickle-bed reactors except for the direction of flow. In bubble column reactors, flow is upward; liquid fills the void space, and the catalyst is completely wetted. Ebulliated bed reactors are similar except that the catalyst is fluidized by high gas and liquid flow rates. This type of reactor is used in H-oil and H-coal processes (see also → Coal Liquefaction, Chap. 3.9.5.).

1.4. Hydrogenation of Individual Compounds

Alkynes. Alkynes are adsorbed on a catalyst surface much more strongly than the corresponding alkenes, thus permitting selective hydrogenation of traces of alkynes in massive amounts of alkenes. Hydrogenation of trace alkynes, usually over a low percentage of palladium on an alumina support with restricted hydrogen supply, is used widely to purify various alkene-containing streams.

The strong adsorption of alkynes also permits selective reduction to the cis alkenes in high yield, a reaction used in the production of a variety of fine chemicals, such as vitamins A and K, prostaglandins, and pheromones. The Lindlar catalyst (Pd – Pb on $CaCO_3$), with or without additional modifiers, is often used for this selective reduction. Ideally, the reaction comes to a

virtual halt after absorption of 1 mol of hydrogen, but terminating the reaction after consumption of the stoichiometric amount of hydrogen may be necessary. The largest volume hydrogenations are of alkynols and alkynediols. Butane-1,4-diol [*110-63-4*], derived from acetylene, has long been made by hydrogenation of butynediol over a base-metal catalyst such as nickel – copper – manganese on silica (→ Butanediols, Butenediol, and Butynediol, Chap. 1.3.). Nickel, the major component, is an effective catalyst for hydrogenation of both acetylenic and olefinic bonds. At the butenediol stage, some aldehyde is formed by rearrangement; this is removed effectively by copper. A small amount of manganese stabilizes the structure. The active binary catalyst palladium – ruthenium on carbon behaves in similar fashion.

Alkenes. Hydrogenation of olefins has extensive industrial application. Dripolene, or pyrolysis gasoline, is stabilized against oxidation by selective reduction of dienes in a complex mixture of olefins and aromatics. The preferred catalyst consists of pellets of palladium on alumina. If the aim of reduction is to produce gasoline, olefins are preserved to boost the octane rating, but if the product is to be used as a source of pure aromatics, olefins are removed in a second stage over a base-metal catalyst, such as nickel or cobalt – molybdenum. Two steps are used for complete olefin hydrogenation, because the more vigorous conditions required for complete reduction cause severe fouling of the catalyst by polymerization of the diene.

The largest single application of olefin hydrogenation is the partial hydrogenation of natural oils to produce margarine, shortening, toppings, salad oil, and other edible products (→ Margarines and Shortenings). A huge market also exists for products derived by more complete hydrogenation; the problem of selectivity described below is not present.

Edible products are derived by partial hydrogenation of various oils (e.g., cottonseed, soybean, sunflower, and rapeseed oil) all of which are glycerides of long-chain saturated and cis-unsaturated fatty acids (→ Fats and Fatty Oils, Chap. 4.3.). Partial hydrogenation of these products improves oxidative stability and alters plastic properties suitably. Oxidative instability is caused primarily by the presence of various homoconjugated dienes and trienes, and an aim of hydrogenation is preferential removal of multiple unsaturation. This task is facilitated by the tendency of hydrogenation catalysts to isomerize homoconjugated into conjugated olefins; the latter, relative to monoenes, are strongly adsorbed on the catalyst. Catalysts differ widely in their ability to promote isomerization, and a close parallel exists between this ability and the selective removal of polyunsaturation. As a consequence of double-bond migration, isomerization of the naturally occurring all-cis olefins into trans olefins may or may not occur, depending on the conformation of the chain at the time of migration. Many catalysts have been studied for these reactions, but industrial practice overwhelmingly favors some form of nickel. Hydrogenation of edible oils is carried out almost entirely in batchwise slurry operation at 140 – 190 °C and 0.2 – 0.3 MPa.

Notwithstanding the huge volume of product, processing is largely carried out in a slurry batch mode. Continuous fixed-bed operation is made difficult by intermittent production, variable feedstocks, and the problem of adjusting conditions to compensate for declining catalyst activity.

Aromatic and Heteroaromatic Rings. Compounds with aromatic or heterocyclic rings are hydrogenated readily and usually without difficulty if other reducible groups are absent. Cyclohexane [*110-82-7*] is obtained mainly by hydrogenation of sulfur-free benzene over supported fixed-bed nickel or platinum catalysts (170 – 230 °C, 2.5 MPa, → Cyclohexane, Chap. 4.1.). The reaction is reversed at higher temperature, which sets an upper limit to a permissible operating temperature of ca. 230 °C. With catalysts of controlled acidity, the product can be obtained virtually free of benzene and methylcyclopentane. Tetralin [*119-64-2*] is produced by hydrogenation of naphthalene over nickel sulfide or nickel – molybdenum at 400 °C and 2 – 6 MPa; a higher pressure gives decalin.

Hexahydrobenzoic acid [*98-89-5*], an intermediate for caprolactam (nylon 6 monomer), is made by hydrogenation of benzoic acid over palladium on carbon powder by using the product as solvent to help prevent excessive temperature (→ Caprolactam, Chap. 4.3.). When only base-metal catalysts were available, this was consid-

ered a very difficult reduction; base-metal catalysts are attacked by the carboxylic acid function.

An important monomer 1,4-bis(hydroxymethyl)cyclohexane is made by two-stage hydrogenation of dimethyl terephthalate. The first stage (160 – 180 °C, 30 MPa), carried out in a fixed-bed reactor over supported palladium, produces dimethyl hexahydroterephthalate. Part of this product is recycled to moderate the temperature increase resulting from the highly exothermic hydrogenation (197.6 kJ/mol). The second stage uses a copper chromite catalyst under similar conditions.

Perhydrogenated rosins are made by hydrogenation of rosin. Rosins contain dehydroabietic acid and similar compounds, which are difficult to reduce. The preferred catalyst is palladium, because it causes the least amount of unwanted decarbonylation and decarboxylation, reactions that lead to catalyst inhibition through competing adsorption with carbon monoxide for catalyst sites [11].

Cyclohexanone [*108-94-1*] is produced by hydrogenation of phenol either in the vapor phase or in a liquid slurry over supported palladium catalysts (→ Cyclohexanol and Cyclohexanone, Chap. 3.1.). In the latter, purified phenol and catalyst slurry enter the first of several reactors and are exposed to synthesis gas (75 % N_2, 25 % H_2). A controlled pressure drop between the reactors ensures forward flow without the need for pumps. The product with the lowest boiling point, cyclohexanone, is removed as vapor in the gas flow. In the last reactor, conversion of phenol is about 95 % complete. Slurry emerging from the last reactor is centrifuged, and recovered catalyst is returned for recycling. Reactor temperature is held between 155 and 170 °C, pressure at 0.5 – 1.4 MPa [12].

Carbonyl Compounds. Aldehydes and ketones behave similarly on hydrogenation, and the same order of catalyst activity usually applies to both functional groups. The difference between aromatic and aliphatic carbonyls is marked, however, and the preferred catalysts differ.

Aliphatic carbonyl compounds are reduced to the corresponding alcohols with little danger of overhydrogenation. Alcohols are in fact an excellent solvent for hydrogenation, even under vigorous conditions.

Hydrogenation of mesityl oxide [*141-79-7*] is a good example. Formed by aldol condensation of acetone, mesityl oxide can be quantitatively reduced to methyl isobutyl ketone (MIBK) over palladium; if desired, MIBK can be reduced further to 4-methylpentan-2-ol over base metals such as nickel or copper.

The first two steps can be combined by employing a dual-functional catalyst, i.e., one capable of catalyzing both condensation and hydrogenation; examples include palladium on zirconium phosphate or on a zeolite.

2-Ethylhexanol [*104-76-7*] an important chemical widely used in plasticizers, is also derived from aldol condensation, followed by hydrogenation of the resulting 2-ethyl-2-hexenal.

Reduction is usually carried out in two stages over supported nickel, with the carbon – carbon double bond reduced first, followed by the aldehyde. One-stage reduction is also performed, but

the two-stage process makes temperature control easier and yields better product quality (see also → 2-Ethylhexanol, Chap. 3.).

Sorbitol [*50-70-4*] is produced on a large scale by hydrogenation of D-glucose over a nickel or ruthenium catalyst. Sorbitol is used in a variety of foods, pharmaceuticals, and cosmetics, as well as in the production of polyurethanes, resins, and vitamin C.

This hydrogenation is not without complications. The temperature must be high enough to give acceptable rates, but not so high as to produce various byproducts resulting mainly from cyclization. The process must be operated within a narrow pH range. Nickel catalysts are damaged if the solution becomes too acidic. If the solution becomes too alkaline, gluconic acid is produced by the Cannizzaro reaction, and mannitol is formed through epimerization at the α-carbon [13].

Aromatic carbonyl compounds are reduced easily, and either reduction to the carbinol or loss of the hydroxyl group can be achieved at will.

Both reactions provide a rich source of products and intermediates in the synthesis of fine chemicals. Palladium is often the catalyst of choice for either hydrogenation or hydrogenolysis. The same catalyst can be used in both steps; in neutral media, both the mechanistic and the thermodynamic selectivities toward the alcohol are very high. The reactions are usually conducted in the presence of small amounts of strong acid when the hydrogenolysis product is desired.

Nitro Compounds. Most nitro compounds are reduced in slurry reactors, although nitrobenzene itself is converted to aniline [*62-53-3*] in vapor-phase fixed-bed reactors as well as in fluidized beds. Catalysts for vapor-phase hydrogenation vary with the producer and include sulfided nickel chromates, nickel – aluminum, silver – manganese oxide, and copper – silica. The reaction temperature is high (300 – 475 °C), and the pressure is 0.5 – 1.5 MPa [14]. Aniline is also produced in continuous slurry reactors by using palladium on carbon black promoted by platinum and iron, palladium on activated carbon or nickel on silica [14] (see also → Aniline, Chap. 3.2.).

The course of hydrogenation of nitroaromatic compounds is complex, and a variety of products can be obtained. Partial hydrogenation yields phenylhydroxylamines. Reaction is best under mild conditions in neutral media with platinum on carbon, inhibited by addition of dimethyl sulfoxide to prevent overhydrogenation [15].

Phenylhydroxylamines are key intermediates in several important processes. In aqueous acid solution, phenylhydroxylamine rearranges to yield 4-aminophenol. If the hydrogenation of nitrobenzene is carried out in sulfuric acid, the intermediate phenylhydroxylamine can be made to rearrange as it forms. This process has become the preferred route to 4-aminophenol [*123-30-8*] (see also → Aminophenols). The hydroxylamine is susceptible to further hydrogenation, a reaction whose rate must be made minimal relative to the rate of rearrangement.

The preferred catalyst for this process is platinum on carbon. Carbon is inert to the hydrolytic environment, and platinum is resistant to attack by acid, as well as being the most effective catalyst for converting nitrobenzene to the hydroxylamine.

Reduction of nitrobenzene in aqueous sodium hydroxide solution over platinum on carbon as catalyst is used to produce hydrazobenzenes. Sodium hydroxide promotes coupling between the intermediates, nitrosobenzene and phenylhydroxylamine. The coupling reaction with subsequent benzidine rearrangement is a useful source of diaminobiphenyls [16].

Diaminotoluene is produced by hydrogenation of dinitrotoluene in the liquid phase by using supported palladium or nickel catalyst. Depending on the producer, conditions vary widely: 50 – 130 °C and 0.2 – 20 MPa. The product is converted mostly to toluene diisocyanate for use in polyurethanes.

Hydrogenation of Nitrate Ion. The hydrogenation of nitrate ion in phosphoric acid or of nitrogen monoxide in sulfuric acid provides large-scale routes to hydroxylamine [*7803-49-8*] an intermediate for caprolactam (see also → Hydroxylamine, Chap. 4.1.). The latter process produces 0.9 t of ammonium sulfate (a sometimes unwanted byproduct) per ton of caprolactam; the former, the hydroxylamine – phosphate – oxime (HPO) process, produces none, and employs novel chemistry and engineering (→ Caprolactam). Reduction is carried out in a slurry with an aqueous solution of 20 % phosphoric acid and 20 % ammonium nitrate over palladium on activated carbon, promoted by germanium dioxide, an unusual promoter. The reduced solution is filtered through a bank of filter sticks mounted within the hydrogenator. The filtrate then passes in countercurrent fashion into a cyclohexanone –toluene mixture to form cyclohexanone oxime in toluene; the depleted aqueous solution is returned to the hydrogenator and enriched with more nitrate for further reaction [17].

Nitriles. Catalytic hydrogenation of nitriles yields a number of products, including primary, secondary, and tertiary amines, aldehydes, and alcohols. All of these products arise from intermediate imines.

$$RCN \xrightarrow{H_2} RHC{=}NH \xrightarrow{H_2} RCH_2NH_2$$

The primary amine formed in this sequence can give an addition product with the imine, which is converted to a secondary amine, either by elimination of ammonia and subsequent hydrogenation, or by direct hydrogenolysis.

$$2\,RCN \xrightarrow{H_2} \underset{\underset{NHCH_2R}{|}}{RCHNH_2} \xrightarrow{H_2} RCH_2NHCH_2R + NH_3$$

Tertiary amines are formed similarly from the addition of a secondary amine to an imine. Aldehydes are obtained in good yield by hydrogenation of a nitrile in aqueous media.

$$RCN \xrightarrow{H_2} RHC{=}NH \xrightarrow[H_2O]{H^+} RCHO + NH_4^+$$

Reduction of a nitrile in the presence of an added amine permits the formation of unsymmetrical amines.

$$R^1CN + R^2NH_2 \xrightarrow{H_2} R^1CH_2NHR^2 + NH_3$$

The major product obtained in the hydrogenation of nitriles depends strongly on the catalyst. For instance, hydrogenation of low molecular mass aliphatic nitriles over rhodium gives secondary amines in high yield, whereas excellent yields of tertiary amines are obtained by reduction over platinum or palladium.

Primary amines are formed from nitriles most easily by hydrogenation carried out in the presence of ammonia. The latter prevents secondary amine formation by competitively reacting with the intermediate imine.

$$RCN + NH_3 + H_2 \longrightarrow \underset{\underset{NH_2}{|}}{RCHNH_2} \xrightarrow{H_2} RCH_2NH_2 + NH_3$$

Cobalt, nickel, and iron are useful catalysts for the hydrogenation of nitriles; reduction over these catalysts is usually carried out under vigorous conditions. Platinum-group catalysts operate under mild conditions and are used in the production of fine chemicals.

Adiponitrile. A much studied and used reduction of nitriles is the synthesis of hexamethylenediamine [*124-09-4*] from adiponitrile (see also → Hexamethylenediamine, Chap. 4.). Hexamethylenediamine is a monomer of nylon 66, as well as an intermediate in the production of diisocyanates used for foams and resins. Reduction of dinitriles presents special problems: secondary amine formation can, in principle,

continue indefinitely, resulting in higher molecular mass compounds that cause catalyst fouling and a loss in yield. Additionally, intramolecular coupling can occur to produce hexamethyleneimine. Both of these reactions are suppressed by ammonia. Hydrogenation of adiponitrile also produces small amounts of 1,2-diaminocyclohexane, which is unusual in that carbon–carbon rather than carbon–nitrogen bond formation takes place. Cobalt, nickel, or iron catalysts are used at high temperature and pressure (100–180 °C, 30–60 MPa). Smaller quantities of the higher homologues of adiponitrile are produced in similar fashion.

Reductive Alkylation and Amination. Reductive alkylation is the term applied to the process of attaching alkyl groups derived from an aldehyde or ketone to ammonia or to primary and secondary amines. The term is also applied to those compounds that are not amines or carbonyls but are converted to them in the course of reduction. Reductive alkylation is a two-step process in which the amine and the carbonyl first react to give an intermediate that is converted to the final product either by elimination of water and subsequent hydrogenation of the resulting imine, or by direct hydrogenolysis of the addition product.

Nickel, rhodium, palladium, platinum, and Raney cobalt have all been used for industrial alkylation. Palladium and platinum are equally effective when reduction is carried out with small molecules (e.g., formaldehyde or acetone), but as the molecule increases in size, platinum becomes the better catalyst. Sulfided nickel, platinum, or rhodium catalysts are very effective for reductive alkylation. These catalysts can be used with lower quality feedstocks because they are more resistant to poisoning than nonsulfided catalysts; furthermore, they have a diminished tendency to reduce the carbonyl to an alcohol and are useful in reductive alkylation when dehydrohalogenation must be avoided, as in the conversion of halonitroaromatics to N-alkylated haloanilines [18].

Reductive alkylation is used widely for the synthesis of alkylated anilines. Compounds of this type are important antioxidants (→ Antioxidants).

Either the aniline or the nitro compound makes a suitable reactant; both are used industrially.

Carboxylic Acids and Esters. Carboxylic acids and their esters are reduced only with difficulty; both require vigorous conditions, unless activated. Rhenium and ruthenium have been used to reduce carboxylic acids at 20–100 MPa and up to 300 °C. Decarboxylation occurs as a side reaction, the extent increasing with increasing temperature. Carboxylic esters are reduced more easily than free acids; the latter tend to attack both the equipment and the catalyst. Copper chromite catalysts are often used for the hydrogenolysis of esters.

An industrial route to the important monomer butane-1,4-diol [*110-63-4*] involves esterification of maleic anhydride with ethanol to obtain diethyl maleate, and hydrogenolysis of the diester over copper chromite; butyrolactone and tetrahydrofuran are byproducts. The relative amounts of these products can be controlled by reaction conditions. The equilibrium ratio of butyrolactone and butane-1,4-diol depends markedly on pressure: at 0.1 MPa and 270 °C, butyrolactone is highly favored; at 30 MPa, the diol is favored in the ratio 94 : 6 (see → Butyrolactone).

Fatty alcohols are produced in large volume by hydrogenolysis of fatty acids, or preferably their esters, under vigorous conditions (275–300 °C, 20–26 MPa). Reduction of acids requires the use of corrosion-resistant equipment; ester reduction is carried out in carbon steel equipment. Natural triglycerides are suitable substrates, but methyl esters are preferable. The latter allows easy separation of the product alcohols and avoids problems connected with high-temperature decomposition of glycerol. Catalysts are usually a type of copper chromite. These reduce double bonds as well as ester groups so that saturated alcohols are produced regardless of starting material. Unsaturated fatty alcohols are produced by hydrogenation of unsaturated esters over cadmium-based

catalysts at a temperature lower than that normally used in ester reduction (→ Fatty Alcohols, Chap. 2.3.3.2., → Fatty Alcohols, Chap. 3.).

2. Dehydrogenation

Dehydrogenation is an important industrial reaction, although the numbers of applications are few compared to hydrogenation. The lesser use of dehydrogenation stems from several aspects of its chemistry.

Dehydrogenation is an endothermic reaction, and the high temperature necessary to obtain a useful conversion to the dehydrogenated product restricts the reaction to those substrates and products with suitable thermal stability. In general, industrial dehydrogenation falls into one of the following categories: (1) the acceptable product is a complex mixture, as in the mixture of olefins obtained from alkane dehydrogenation, used for detergent alkylate; (2) an unsaturated system is extended, as in the conversion of benzene to biphenyl or ethylbenzene to styrene; (3) aromatization occurs, a reaction that provides a driving force as well as a convenient stopping place; (4) a point of attack exists, as in the conversion of methanol or ethanol to formaldehyde or acetaldehyde, respectively; (5) the choice of product is limited, as in the conversion of butane or butene to butadiene [9].

2.1. Styrene

Styrene [*100-42-5*], an important monomer, is obtained largely by dehydrogenation of ethylbenzene in the presence of superheated steam (→ Styrene).

The catalyst for this reaction usually contains some major active ingredient, a stabilizer, and an alkali-metal promoter. Common commercial catalysts contain iron oxide promoted by potassium and a structural stabilizer. Potassium is a very effective promoter and increases the reaction rate by an order of magnitude. Potassium is volatile under reaction conditions and moves toward the reactor exit; redistribution of potassium occurs within the catalyst particles as well. Styrene formation is endothermic, and as a consequence, the center of a catalyst pellet in use becomes cooler than the edges; this temperature gradient causes inward migration of potassium, resulting in catalyst deactivation near both the center and the edges due to excess and deficient potassium, respectively.

Superheated steam plays an important role in styrene production and serves several purposes: it is introduced directly into the reactor in large molar excess to provide part of the necessary heat to drive the endothermic reaction; it serves as an oxidant to maintain the iron oxide catalyst in the appropriate oxidation state and removes carbonaceous deposits from the catalyst through the water – gas shift reaction; it reduces the partial pressure of hydrocarbons, thereby increasing conversion to styrene. Optimum conversion is determined by the balance between the advantage of increased conversion and the cost of increased steam. Over the last two decades, improved processing has permitted a continual decrease in the molar ratio of steam to hydrocarbon. The ratio is between 6 and 12, with 65 – 70 % conversion and 90 – 95 % selectivity, at 600 – 650 °C and 51 – 101 kPa. Some reactors operate in an isothermal mode, heat being supplied by a heat-transfer medium on the outside of the reactor tubes, which offers the advantage of reduced steam requirements; however, this advantage is offset by higher capital costs. Most processes operate in the adiabatic mode. In practice, conversion is limited by the equilibrium between styrene, ethylbenzene, and hydrogen. As styrene approaches equilibrium concentration, its rate of formation decreases but the rate of byproduct formation does not; the yield, therefore, falls with increased conversion [19], [20]. The limitation on conversion can be cirumvented if the reaction is run as an oxidative dehydrogenation, (i.e., with oxygen present to combine with liberated hydrogen and remove it from the equilibrium). Despite much effort, no large-scale plant operates in this mode.

The technology of ethylbenzene dehydrogenation has been extended to produce both α-methylstyrene and divinylbenzene by dehydrogenation of cumene and diethylbenzene, respectively.

2.2. Dehydrogenation of *n*-Alkanes

Olefins are hydrogenated easily and quantitatively to alkanes under ambient conditions, but the reverse reaction is not achieved as readily. In hydrogenation, the olefinic function provides a point of attack and the stability of the alkane product provides automatic termination. Alkanes, on the other hand, have no unique point of attack, and the alkene resulting from dehydrogenation is more easily dehydrogenated than the starting material itself. Moreover, at ambient conditions, the equilibrium between alkane and alkene lies completely in favor of the alkane [21]. Alkenes begin to appear in traces only at 300 °C; at least 400 °C is required for more substantial conversion (ca. 10 %). The high temperature necessary for alkene formation also favors side reactions such as polymerization and cracking.

Dehydrogenation of alkanes is greatly helped by a suitable catalyst where it is thermodynamically possible at a temperature below that of thermal decomposition. Propane, butane, and alkanes in the detergent alkylate range (ca. C_{10} – C_{14}) have all been catalytically dehydrogenated on a large scale. Little advantage is gained by catalysis in the dehydrogenation of C_2 hydrocarbons, because the equilibrium is unfavorable at a temperature below that required for thermal decomposition.

Cracking (cleavage of the carbon – carbon bond) is energetically favored over cleavage of the carbon – hydrogen bond, and catalysts such as nickel, which are excellent for hydrogenation of alkenes, lead to extensive formation of methane when applied to dehydrogenation.

The reaction expressing the general alkane – alkene equilibrium is

$$C_nH_{2n+2} \rightleftharpoons C_nH_{2n} + H_2$$

Alkenes are favored by lower pressure, as expressed by the equation

$$C^2/\left(1-C^2\right) = K/p$$

where C is the fraction dehydrogenated, K is the equilibrium constant, and p the pressure in atmospheres. This equation holds for the conversion of alkanes to monoenes and of monoenes to dienes. Conversion of alkanes to dienes (e.g., butane to butadiene)

$$C_nH_{2n+2} \rightleftharpoons C_nH_{2n-2} + 2\,H_2$$

is related to pressure by the equation

$$4C^3/(1-C)\,(1+2C)^2 = K/p^2$$

Conversion is increased by operation at lower pressure or by use of a diluent.

Butenes and butadiene are produced by dehydrogenation of butane, although the process finds increasing competition from oxidative dehydrogenation and from thermal cracking (→ Butadiene, Chap. 4.; → Butenes, Chap. 4.). Operating conditions vary: the temperature is 550 – 650 °C and the pressure 30 – 300 kPa, contact times are a few seconds. Catalysts coke rapidly and are oxidatively regenerated every 10 – 100 min. By mixing the catalyst with inert material, much of the heat liberated during oxidation can be captured and used to drive the endothermic dehydrogenation. Most catalysts in this service are based on chromia – alumina. These catalysts are strongly inhibited by water vapor; the butane feed must, therefore, be dried carefully.

Other catalysts, such as nickel – calcium phosphate stabilized with chromia, iron oxide promoted by potassium, and chromium oxides, require the presence of steam to help keep the catalyst in the proper oxidation state. Excessive coking occurs if these catalysts become reduced. Steam also acts as a source of heat and shifts the conversion toward the dehydrogenated product by lowering the partial pressure of the latter.

2.3. Catalytic Reforming of Hydrocarbons

The objective of catalytic reforming is the conversion of saturated hydrocarbons to aromatics as selectively as possible. This process is the chief source of high-octane fuel and of aromatic hydrocarbons. Catalytic reforming involves a complex series of reactions in which dehydrogenation figures prominently. Catalysts are dual-functional, having both a metallic element to catalyze dehydrogenation – hydrogenation and an acidic function to catalyze hydrocarbon rearrangements. Catalysts typically contain a small amount of highly dispersed platinum (<1 %)

supported on alumina (150 – 300 m^2/g), as well as a second metal such as rhenium. Polymetallic catalysts permit operation under more severe conditions; they also possess improved stability and activity.

Typical operating conditions are 430 – 530 °C and 1.0 – 3.5 MPa. A unit consists of several, frequently four, fixed-bed reactors in series. Heated naphtha enters the first reactor, where the major reaction is endothermic dehydrogenation of cycloalkanes accompanied by a decrease in temperature. The effluent is reheated and the process continued for all reactors. The liquid product contains 60 – 70 wt % aromatics; the gaseous product contains light hydrocarbons admixed with 60 – 90 mol % hydrogen. The gaseous portion is recycled to the first reactor in a ratio of 5 – 10 mol of recycle gas per mole of naphtha to maintain a high partial pressure of hydrogen in the system. The presence of hydrogen diminishes the yield of aromatics, but hydrogen is necessary to maintain catalyst activity by retarding formation of hydrocarbon residues that poison the catalyst. An aim of processing is operation at as low a partial pressure of hydrogen as possible, commensurate with good catalyst life.

Dehydrogenation of cyclohexanes is the most facile of all reactions that occur in reforming. On the other hand, only traces of olefins can be formed by dehydrogenation of alkanes under reforming conditions, because of an unfavorable equilibrium. Nonetheless, dehydrogenation is of considerable importance because olefins appear to be intermediates in the overall process [22].

2.4. Liquid-Phase Dehydrogenation

The constraints imposed on dehydrogenation by equilibrium considerations can be loosened if hydrogen is removed from the products as they are formed. Dehydrogenation in the liquid phase in an open vessel fulfills this goal. Hydrogen escapes from the system, whereas products and reactants remain in the vessel or are returned after condensation. The lower temperature limit is then set not by the equilibrium but by a convenient reaction rate.

In practice, the substrate, neat or dissolved in an inert solvent of convenient boiling point, is refluxed in the presence of catalyst. Hydrogen escapes while other volatile products are condensed and returned, with or without removal of the product. If the product is removed, the operation can be made continuous.

All the considerations involving the influence of mass transport on the rate of reaction (see Section 1.1) apply in reverse to dehydrogenation. Good stirring helps to remove liberated hydrogen from the vicinity of the catalyst, and reflux facilitates hydrogen removal from the liquid. If the substrate or product is thermally unstable at normal reflux temperature, the temperature can be lowered by reducing the pressure. Liquid-phase dehydrogenation is used in the production of a number of fine chemicals of limited thermal stability.

Dehydrogenation may be facilitated by the use of a hydrogen acceptor to remove hydrogen from the system as it is formed [23].

The hydrogen transfer reaction above may be written generally as follows:

$$AH_2 + B \longrightarrow A + BH_2$$

These hydrogenation – dehydrogenation reactions are useful for carrying out hydrogenations in places where hydrogen is unavailable or its use is not permitted; only simple equipment is required [24]. Hydrogen transfer reactions often give better yields of hydrogenated products than are obtained by direct hydrogenation.

1. Introduction

Hydroquinone (**1**) [*123-31-9*] (1,4-benzenediol, 1,4-dihydroxybenzene, *p*-dihydroxybenzene, hydroquinol, quinol), $C_6H_6O_2$, M_r 110.11, first described in 1844 by WOEHLER, was obtained by the addition of hydrogen to 1,4-benzoquinone.

1

Hydroquinone occurs naturally as hydroquinone β-D-glucopyranoside (arbutin) in the leaves of several plants, including bearberry, cranberry, cowberry, and some varieties of pear [1], usually accompanied by its methyl ether, methylarbutin. Arbutin is easily hydrolyzed to hydroquinone and glucose in hot, dilute aqueous acid; hydrolysis of methylarbutin produces hydroquinone monomethyl ether and glucose.

2. Physical Properties

Hydroquinone is a colorless crystalline solid when pure. Three crystalline modifications exist: the stable α-form, *mp* 173.8 – 174.8 °C, is obtained as hexagonal needles by crystallization from water; the labile γ-form, *mp* 169 °C, is obtained as monoclinic prisms by sublimation; the labile β-modification is obtained as needles or prisms by crystallization from methanol or isopropyl alcohol.

Commercial grades of hydroquinone are typically white to off-white crystalline materials; solutions of hydroquinone are discolored by oxidation on contact with air. Physical constants and solubility data are listed in Table 1. Various spectra of hydroquinone are readily available: IR (prism) [2, a], IR (grating) [2, b], ^{13}C NMR [2, c], proton NMR [2, d], UV [2, e], and FTIR [3].

3. Chemical Properties

Hydroquinone is easily converted by most oxidizing agents to *p*-benzoquinone [*106-51-4*] (→ Benzoquinone); even neutral aqueous solutions of hydroquinone darken on exposure to air. The rate of oxidation of hydroquinone by air is accelerated in alkaline solution. The oxidation product can add water to give 1,2,4-benzenetriol; subsequent oxidation may result in the formation of humic acids.

The redox potential E_0 of hydroquinone is 699 mV [5]; the half-wave potential $E_{1/2}$ is 560 mV at pH 0 [5] and 234 mV at pH 5 – 6 [6]. Oxidation of hydroquinone involves loss of an electron and elimination of a proton to give the relatively stable semibenzoquinone radical (**2**). The ability of hydroquinone to act as an antioxidant is a consequence of the formation and stability of this radical. A second one-electron transfer and proton elimination results in the formation of *p*-benzoquinone (**3**).

Hydroquinone and *p*-benzoquinone form the equimolar charge-transfer complex quinhydrone. The quinhydrone complex is typically dark greenish-black, *mp* 171 °C.

Hydroquinone is a reducing agent, whose reduction potential is suitable for reducing silver halide. Grains of silver halide that have been exposed to light are reduced much faster than unexposed or underexposed grains. This property is the basis for the use of hydroquinone as a developing agent in photography (→ Photography). The selectivity is a result of changes in the exposed silver halide crystals, which reduce the energy barrier for reaction with hydroquinone to form elemental silver and *p*-benzoquinone. Sodium sulfite is added to the developing solution to prevent formation of quinhydrone by converting the *p*-benzoquinone to sodium 2,5-dihydroxybenzenesulfonate (**4**), a weaker developing agent than hydroquinone.

4

The reactivity of hydroquinone is generally similar to that of phenol (→ Phenol). One or both hydroxyl groups may be converted to an ether or ester. Commercially important oxygen derivatives include hydroquinone monomethyl ether (**5**) [*150-76-5*], hydroquinone dimethyl ether (**6**) [*150-78-7*], and hydroquinone bis(2-hydroxyethyl) ether (**7**) [*104-38-1*].

5 **6** **7**

Hydroquinone esters undergo the Fries rearrangement to give acyl-substituted hydroquinones.

Hydroquinone and its ethers may be C-alkylated under Friedel – Crafts conditions to produce a variety of mono- and disubstituted products. Among the commercially important alkylated derivatives are 2- *tert*-butylhydroquinone (**8**) [*1948-33-0*], 2,5-bis[2-(2-methylbutyl)]hydroquinone (**9**), and 2-*tert*-butyl-4-methoxyphenol (BHA) (**10**) [*121-00-6*].

8

9

10

Hydroquinone reacts with alkylamines or arylamines to form substituted arylamines. Commercially important products include *p*-*N*-methylaminophenol (**11**) [*150-75-4*], usually marketed as the sulfate salt [*55-55-0*], and *N,N′*-diphenyl-*p*-phenylenediamine (**12**) [*74-31-7*].

11 **12**

Hydroquinone may be chlorinated with chlorine or sulfuryl chloride to provide derivatives that range from mono- to tetrachlorinated. Kolbe–Schmitt carboxylation of hydroquinone with carbon dioxide leads to 2,5-dihydroxybenzoic acid (gentisic acid). Quinizarin [*81-64-1*] (1,4-dihydroxyanthraquinone) can be prepared by the condensation of hydroquinone with phthalic anhydride (see also → Anthraquinone Dyes and Intermediates, Chap. 2.6.1.1.). Catalytic hydrogenation of hydroquinone gives 1,4-cyclohexanediol (quinitol). Sulfonation of hydroquinone results in the formation of hydroquinone mono- or disulfonic acid, usually isolated as the corresponding potassium salt.

4. Production

Table 2. Production of hydroquinone

Process	Capacity, t/a	Major producers/location
Oxidation of *p*-diisopropylbenzene	25 000	Eastman Chemical Products/United States Goodyear/United States Mitsui/Japan
Hydroxylation of phenol	14 000	Rhône-Poulenc/France Enichem/Italy Ube/Japan
Oxidation of aniline	4 000	People's Republic of China
Total world capacity	43 000	

Three processes are used for the industrial production of hydroquinone: hydroperoxidation of *p*-diisopropylbenzene [*100-18-5*], hydroxylation of phenol [*108-95-2*], and oxidation of aniline [*62-52-3*]. The processes, production capacities, and major producers are listed in Table 2. Although other processes are known, they are not industrially important.

4.1. Hydroperoxidation of *p*-Diisopropylbenzene

p-Diisopropylbenzene (*p*-DIPB) is produced by Friedel–Crafts alkylation of benzene with propene (→ Acylation and Alkylation). Purified *p*-DIPB (**13**) is subsequently converted to the dihydroperoxide (DHP) by air oxidation under slightly alkaline conditions at 80 – 90 °C. The DHP (**14**) is separated from the reaction mixture

13 **14** **1**

either by extraction or by crystallization, and is then cleaved to hydroquinone (**1**) and acetone by an acid-catalyzed Hock rearrangement; the DHP solution is treated with sulfuric acid catalyst (0.2 – 1.0 %) at 60 – 80 °C. The hydroquinone is crystallized and isolated. The overall yield of (**1**) (based on *p*-DIPB) is ca. 80 %.

4.2. Hydroxylation of Phenol

The catalyzed hydroxylation of phenol at ca. 80 °C with 70 % aqueous hydrogen peroxide produces a mixture of hydroquinone and catechol (**15**). The catalyst may be a strong mineral acid, iron(II), or a cobalt(II) salt. Depending on catalyst selection, the ratio of catechol to hydroquinone can be varied from 3 : 1 to 0.1 : 1; in practice, the ratio is typically 1.5 : 1, i.e., catechol is the major product. The reaction proceeds by an ionic mechanism in which hydrogen peroxide is polarized by the strong acid catalyst and phenol is subsequently hydroxylated the resulting isomers are separated by a series of extractions and solvent-stripping operations.

15

The ratio of the products hydroquinone and catechol may be influenced by the presence of superacids or shape-selective zeolites. Thus, use of a vanadium–modified Nafion perfluorosulfonate polymer for the oxidation of phenol gave a hydroquinone–catechol ratio of 12.5 : 1 [7]. The use of a shape–selective zeolite in the hydroxylation of phenol has yielded hydroquinone with 99 % selectivity [8].

4.3. Oxidation of Aniline

Oxidation of aniline [*62-53-3*] is the oldest process used for the production of hydroquinone. Aniline is oxidized with manganese dioxide (15 – 20 % excess) in aqueous sulfuric acid at 0 – 5 °C to produce *p*-benzoquinone (**3**). This intermediate is removed from the reaction mixture by steam stripping and collected. A byproduct, manganese sulfate, may be retrieved from the depleted reaction mixture and sold for agricultural applications.

Hydroquinone is obtained from the intermediate *p*-benzoquinone by reduction with iron at 55 – 65 °C or by catalytic hydrogenation. The product (usually technical grade) is crystallized, isolated from the typically aqueous stream by centrifugation, and dried in a vacuum dryer. The overall yield of hydroquinone from aniline is ca. 85 %.

Aniline oxidation is a batchwise process and, therefore, relatively labor intensive. The use of ground manganese ore and finely divided iron leads to extremely abrasive processing conditions; a great deal of maintenance is usually required. Disposal of the inorganic coproducts (amounting to ca. 85 % of the total weight of products) is of environmental concern.

4.4. Other Processes

Carboxylate esters of aromatic diols can be prepared by Baeyer–Villiger oxidation of a 4-hydroxy-substituted aromatic ketone with 97 % conversion and 97 % efficiency [9]. Microbiological oxidation of either benzene or phenol produces hydroquinone with very high selectivity [10]. Copper-catalyzed air oxidation of phenol provides *p*-benzoquinone in greater than 90 % selectivity [11]. Benzene has been oxidized to hydroquinone in the presence of copper(I) chloride [12] or titanium [13]. Oxidation of benzene in aqueous solution with ozone gives *p*-benzoquinone and hydroquinone [14].

Other preparative methods include the reaction of *p*-isopropenylphenol with 30 % aqueous hydrogen peroxide under acidic conditions [15]; *p*-isopropenylphenol may be obtained from bisphenol A [*80-05-7*] by alkaline cracking. Hydroquinone can also be produced by the carbonylation of acetylene [16], [17]; catalytic hydrogenation of nitrobenzene in acidic solution [18]; acid hydrolysis of nitrobenzene [19] or *p*-nitrosophenol [20]; and electrochemical oxidation of benzene or phenol in dilute sulfuric acid, followed by reduction [21], [22].

5. Environmental Protection

An estimate of environmental effects can be obtained from the data available [23–29]. Hydroquinone has a high BOD and can cause oxygen depletion in aqueous systems. It has high potential for affecting some aquatic organisms and moderate potential for affecting microorganisms used in secondary waste treatment. Hydroquinone has a moderate potential to affect the germination or early growth of some plants.

It is readily biodegraded and has a low tendency to concentrate in biological systems. Direct, instantaneous discharge of hydroquinone to a large body of water at a final concentration of 0.005 mg/L or less, followed by secondary waste treatment, is not expected to cause adverse environmental effects.

6. Quality Specifications and Analysis

Five grades of hydroquinone are available: photographic, technical, U.S.P., inhibitor, and polyester. The most important grades (in terms of volume) are photographic and technical. The quality requirements for photographic-grade hydroquinone are defined in American National Standards Institute (ANSI) Specification PH 4.126-1972. Manufacturers specifications for photographic and technical grades are given in Table 3. Specifications for U.S.P.-grade hydroquinone, used in pharmaceutical applications, are described in U.S.P.-XXI [30]. Inhibitor and polyester grades are used in special applications, and the specifications for each grade are provided by the producer. Hydroquinone may be analyzed by a variety of techniques, including spectroscopic, chromatographic, titrimetric, and electrochemical methods.

Table 3. Specifications of hydroquinone

Property	Specifications	
	Photographic [32]	Technical [31]
Appearance	free-flowing white crystals	white to offwhite crystals
mp, °C (min.)	171	169
Assay, wt % (min.)	99.4	99.0
Ash content, wt % (max.)		0.04
pH (5 % aqueous solution)	4.1 – 4.7	
Iron, ppm (max.)	10	
Water, % (max.)	0.6	1.0
Resorcinol, ppm (max.)	50	
Solubility in water		complete
Molar absorptivity ∗ (max).	0.07 (700)	
mL g^{-1} cm^{-1} (λ_{max}, nm)	0.12 (520)	
	0.19 (455)	1.0 (455)

∗ In 0.1 M aqueous hydrochloric acid.

7. Uses

Hydroquinone and its derivatives are used in photographic applications, the rubber industry, monomer inhibitors, dyes and pigments, antioxidants, agricultural chemicals, and other diverse and special applications. Demand for hydroquinone and its derivatives is shown in Table 4, according to market segment. Consumption (in tonnes) of hydroquinone and derivatives by geographical area is as follows:

United States	13 100
Europe	9 600
Japan	3 800
Other	4 800
Total	31 300

The largest demand for hydroquinone is as a photographic developer, principally for black-and-white film, lithography, photochemical machining, microfilm, and X-ray film (→ Imaging Technology, → Photography). Many derivatives of hydroquinone are used in photographic applications, e.g., the sulfate salt of *p*-*N*-methylaminophenol (**11**) and potassium 2,5-dihydroxybenzenesulfonate.

Table 4. Worldwide demand for hydroquinone and its derivatives by market segment (1987)

Market segment	Demand	
	t	% of total
Photography	11 600	37
Rubber industry	8 100	26
Monomer inhibitors	3 100	10
Dyes and pigments	2 800	9
Antioxidants	650	2
Agricultural chemicals	650	2
Others	4 400	14
Total	31 300	100

The second largest consumer of hydroquinone is the rubber industry, which requires hydroquinone for the production of antioxidants and antiozonants (→ Antioxidants). Hydroquinone derivatives used in this area include *N,N′*-diaryl-*p*-phenylenediamines (e.g., *N,N′*-diphenyl-*p*-phenylenediamine), dialkylated hydroquinones, *N*-alkyl-*p*-aminophenols, dialkyl-*p*-phenylenediamines, and aralkyl-*p*-phenylenediamines.

Hydroquinone, hydroquinone monomethyl ether, and *p*-benzoquinone are used extensively in the vinyl monomer industry to inhibit free-radical polymerization during both processing and storage. Hydroquinone, *p*-benzoquinone, 2-methylhydroquinone (toluhydroquinone), 2-*tert*-butylhydroquinone, and 2,5-di-*tert*-butylhydroquinone are used as stabilizers for unsaturated polyester resins. Food-grade antioxidants include 2-*tert*-butylhydroquinone (**8**) and 2-*tert*-butyl-4-methoxyphenol (**10**) (→ Antioxidants, Chap. 5.1.).

Hydroquinone dimethyl ether (**6**) is used as a starting material for a family of dyes and pigments based on the 2-amino- and 2-amino-5-chloro derivatives. Quinizarin is an intermediate for textile dyes (→ Anthraquinone Dyes and Intermediates). The fungicide Chloroneb is produced from (**6**) as raw material. The herbicide ethofumesate is produced from *p*-benzoquinone. Fluazifop-butyl [33] is representative of a new family of herbicides based on the *o*-alkylation of hydroquinone with 2-halopropionic acid derivatives [34–37].

Hydroquinone bis(2-hydroxyethyl) ether (**7**), the product of the reaction of hydroquinone with ethylene oxide, is used as a chain extender in thermosetting urethane polymers [38].

Hydroquinone (U.S.P. grade) and several derivatives are used in topical formulations as skin bleaching and depigmenting agents.

Several new applications for hydroquinone and its derivatives are emerging. The oxygen-scavenging properties of hydroquinone are being exploited for use in boiler water treatment [39]. Hydroquinone and certain C-alkylated or Carylated derivatives are useful monomers for the preparation of a variety of polymers, including liquid crystal polyesters for high-performance plastics, composites, and fibers. In addition to high tensile and impact strengths, these materials exhibit good weatherability, solvent resistance, flame retardance, transparency to microwave radiation, and retention of strength at elevated temperature [40], [41].

8. Toxicology and Occupational Health

Acute toxicity data are shown in Table 5. In a two-year study of rats receiving a diet containing up to 1 % hydroquinone, no effects were observed on final body weight, hematology, or pathology; at 5 % in the diet, a 46 % weight loss together with toxic effects on the bone marrow and liver was found within nine weeks [43]. When applied to the skin of mice, hydroquinone was not carcinogenic and did not promote the carcinogenic activity of benzo[*a*]pyrene [44]. In a skin-painting study in rats, croton oil failed to promote any carcinogenicity from hydroquinone [45]. Hydroquinone produced a negative response in the *Salmonella* bacterial mutagenesis assay [46]. Positive results were observed in the micronucleus test [47] and in an in vitro test for sister chromosome exchanges in human lymphocytes [48].

Table 5. Toxicity data for hydroquinone [23]

Test	Species	Result
Acute oral LD_{50}	rat	400 mg/kg
Acute oral LD_{50}	mouse	100 – 200 mg/kg
Dermal LD_{50}	guinea pig	> 1000 mg/kg
Skin irritation	guinea pig	slight
Eye irritation	rabbit	moderate erythema, clearing by day 14
Sensitization (guinea pig)		
Freund's adjuvant		3/10 slight
Modified Buhler		7/15 low, 2/10 moderate
Maximization [42]		70 % sensitized, strong

Maternal toxicity and fetotoxicity were observed in pregnant rats given 300 mg/kg of hydroquinone daily, but no compound-related teratogenic effects occurred; no adverse effects were observed at doses up to 100 mg/kg per day [23]. Rats given a single dose of 200 mg/kg of (^{14}C)hydroquinone excreted 91.9 % in the urine within 2 – 4 d, 3.8 % in the feces, and 0.39 % in expired air, with 1.25 % remaining in the body; radiolabeled compounds identified in the urine included hydroquinone monoglucuronide (56 – 66 %), hydroquinone monosulfate (25 – 42 %), and hydroquinone (1.1 – 8.6 %) [49]. The percutaneous absorption rate of (^{14}C)hydroquinone in beagles was ca. 1.1 $\mu g\,cm^{-2}\,h^{-1}$, indicating that hydroquinone is poorly absorbed through the skin [23].

The OSHA Permitted Exposure Limit (PEL) and ACGIH Threshold Limit Value (TLV) for hydroquinone is 2 mg/m^3 TWA. Effects of hu-

man exposure are well documented (see below). Direct contact of hydroquinone dust and quinone vapor with the eye may cause irritation. Chronic exposure at high levels has caused brownish discoloration of the cornea and conjunctiva, as well as distortion of the cornea, leading in some cases to decreased visual acuity and even blindness. Exposure to levels below the TLV of 2 mg/m^3 has not produced these effects [50].

A low incidence of allergic contact dermatitis has been reported from handling large amounts of hydroquinone, where exposure to dust occurred, and from repeated contact with alkaline photographic developer solutions [23]. Skin sensitization was noted in 2 members of a group of 48 middle-aged males who used a depigmentation ointment containing 5 % hydroquinone; 38 subjects treated with a 2 % ointment and 26 subjects treated with a 3 % ointment showed no sensitization [51], [52].

In reported poisonings, the lethal dosage for adults is 5 – 12 g (70 – 170 mg/kg). Lower doses cause no adverse effects: two men ingested 500 mg/d for five months and 17 men and women ingested 300 mg/d for three to five months without abnormal symptoms or any abnormalities in blood and urine [43].

1. Introduction

Hydroxycarboxylic acids are widely distributed in nature, playing an important role as metabolic intermediates in both plants and animals. Examples can be found in the tricarboxylic acid cycle leading to the degradation (β-oxidation) of fatty acids, as well as in the fermentation of sugars. Hydroxycarboxylic acids are also excreted in the urine, especially in metabolic disorders. Thus, diabetics are incapable of further metabolizing the β-hydroxybutyric acid and acetoacetic acid derived from butyric acid, so these materials are simply eliminated.

One of the first reports of a naturally occurring hydroxycarboxylic acid occurred in 1780 when SCHEELE described the isolation of (*R*)-(−)-lactic acid from soured milk. The substance is formed during the fermentation of lactose by lactobacilli. SCHEELE also discovered *S*-(−)-malic acid (in 1785), *S*-(+)-tartaric acid (in 1769), and citric acid (in 1784) isolating each as its calcium salt. Another member of the group, glycolic acid, is a constituent of unripe fruit, especially grapes. Related natural substances include tartronic, hydroxystearic, mandelic (see → Hydroxycarboxylic Acids, Aromatic), and numerous other fruit- or sugar-derived acids.

Definition In contrast to the purely aromatic hydroxycarboxylic acids (phenolic carboxylic acids), which contain phenolic hydroxyl groups on the aromatic nucleus and thus display enhanced acidity, aliphatic hydroxycarboxylic acids are characterized by purely aliphatic alcohol hydroxyl groups.

Aliphatic hydroxycarboxylic acids may have one or several hydroxyl groups, together with one or more carboxyl groups. In the simplest case, the monohydroxymonocarboxylic acids, the compounds can be conveniently subdivided into three categories:

1) 2- or α-hydroxycarboxylic acids,
2) 3- or β-hydroxycarboxylic acids, and
3) hydroxycarboxylic acids with the hydroxyl group located in the 4- (i.e., γ-) position, or even more remote from the carboxyl group.

Table 1 lists several commercially important hydroxycarboxylic acids and related compounds, grouped in accordance with the above scheme.

2. General Characteristics

The overall characteristics of a hydroxycarboxylic acid are a function of the number of hydroxyl and carboxylic acid groups present as well as their relative placement.

	(*R,S*)-lactic acid	[*598-82-3*]	$CH_3-CHOH-COOH$	90.08
	(*R,S*)-α-hydroxybutyric acid	[*600-15-7*]	$CH_3CH_2-CHOH-COOH$	104.11
One −OH group in the β-position	hydracrylic acid	[*503-66-2*]	$HOCH_2-CH_2-COOH$	90.08
	β-propiolactone	[*57-57-8*]	$CH_2-C=O$; CH_2-O	72.06
	(*R,S*)-tropic acid	[*552-63-6*]	$HOCH_2-CH(C_6H_5)-COOH$	166.18
	(*R,S*)-β-hydroxybutyric acid	[*625-71-8*]	$CH_3-CHOH-CH_2-COOH$	104.11
One −OH group in the γ-position (or more remote)	γ-hydroxybutyric acid	[*591-81-1*]	$HOCH_2-CH_2-CH_2-COOH$	104.11
	γ-butyrolactone	[*96-48-0*]	CH_2-CH_2-O ; $CH_2-C=O$	86.09
	(*R,S*)-ricinoleic acid	[*141-22-0*]	$CH-CH_2-CHOH-C_6H_{13}$; $CH-(CH_2)_7-COOH$	298.45
Two −OH groups	(*R,S*)-glyceric acid	[*600-19-1*]	$HOCH_2-CHOH-COOH$	
Dicarboxylic acids	tartronic acid	[*80-69-3*]	$HOOC-CHOH-COOH$	120.06
One −OH group	(*R,S*)-malic acid	[*617-48-1*]	$HOOC-CH_2-CHOH-COOH$	134.09
Two −OH groups	(*R,S*)-tartaric acid	[*133-37-9*]	$HOOC-CH(OH)-CH(OH)-COOH$	150.09
	meso-tartaric acid	[*147-73-9*]	$HOOC-CH(OH)-CH(OH)-COOH$	150.09
Tricarboxylic acids	citric acid	[*77-92-9*]	$CH_2(COOH)-C(OH)(COOH)-CH_2(COOH)$	192.13

2.1. Physical Properties

Most naturally occurring hydroxycarboxylic acids are chiral and thus exhibit optical activity. In pure form, they are usually crystallizable. Hydroxycarboxylic acids have exceptionally high boiling points relative to corresponding unsubstituted acids with the same chain length. This is a consequence of association among the hydroxyl groups. For this reason, many of these compounds cannot be distilled without decomposition, even under vacuum.

Table 2 summarizes the physical properties of the commercially important hydroxycarboxylic acids and their derivatives listed in Table 1.

2.2. Chemical Properties

Hydroxycarboxylic acids readily form the expected salts at the carboxyl group. The acidity of α- and β-hydroxycarboxylic acids is enhanced relative to the corresponding unsubstituted acids because of the proximity of the polar hydroxyl group. Compounds in this category may be esterified at either the carboxyl or the hydroxyl function by reaction with other alcohols or acids, respectively. The actual course of such reactions depends once again on the placement of the hydroxyl group relative to the carboxylic acid group.

Both α- and β-hydroxycarboxylic acids readily form esters with other alcohol groups but the latter also have a tendency to eliminate water under the reaction conditions. The γ- and

Table 2. Physical properties of the hydroxycarboxylic acids listed in Table .

Hydroxycarboxylic acid	*mp*, °C	*bp*, °C	Density, d_4^{20}	Refractive index, n_D^{20}	$pK_{A_1}^{25}$, (25 °C)
Glycolic acid	78 – 80	100 (decomp.)	1.49 (at 25 °C)		3.81
n-Butyl glycolate		178 – 186 or 82 – 97 (at 2.7 kPa)	1.015 – 1.023	1.423 – 1.4246

(*R,S*)-Tartaric acid	205				3.03
meso-Tartaric acid	159 – 160				3.11
Citric acid	153		1.665		3.13

δ-hydroxycarboxylic acids undergo intramolecular esterification to form lactones, this reaction being faster than intermolecular esterification. Compounds in which the hydroxyl group is more remote from the acid moiety are again subject to normal esterification.

α-Hydroxycarboxylic acids dimerize with elimination of water to produce six-membered cyclic diesters called 1,4-dioxane-2,5-diones according to IUPAC. These are commonly referred to as lactides, because the phenomenon was first encountered with lactic acid.

The process may be accompanied by intermolecular esterification, which produces linear polyesters.

Note that the latter type of esterification, known as *estolide formation,* is not restricted to α-hydroxycarboxylic acids. Another important characteristic of both α- and β-hydroxycarboxylic acids is that the proximity of the two functional groups weakens the intervening C−C bond(s). Thus, treatment of such compounds with sulfuric acid results in the elimination of formic acid, which decomposes in the presence of concentrated sulfuric acid to carbon monoxide and water.

The rest of the chain is converted into aldehydes (in the case of α-hydroxycarboxylic acids) or ketones (in the case of β-hydroxycarboxylic acids) with one fewer carbon atom.

This elimination reaction proceeds so smoothly that it is used for quantitative determination of certain hydroxycarboxylic acids. Thus, lactic acid is converted easily to acetaldehyde, and β-hydroxybutyric acid to acetone. Oxidative cleavage is also possible. For example, treatment of α-hydroxycarboxylic acids with hydrogen peroxide in the presence of iron(II) ions leads to easy elimination of carbon dioxide to produce again aldehydes containing one fewer carbon atom in the chain.

β-Hydroxycarboxylic acids readily undergo intramolecular elimination of water to produce α,β-unsaturated carboxylic acids; e.g.,

Thus, β-hydroxypropionic acid (hydracrylic acid) can be dehydrated to acrylic acid, and β-hydroxybutyric acid to crotonic acid.

The γ- and δ-*hydroxycarboxylic acids* undergo dehydration even at room temperature, yielding γ- and δ-lactones. The corresponding free acid may be regenerated in aqueous alkaline medium, but often it is stable only in the form of its salts. Lactones are internal esters of hydroxycarboxylic acids.

Treatment of a lactone with ammonia produces the corresponding *lactam.*

The related derivatives of α-hydroxycarboxylic acids, the three-membered α-lactones, are unstable and are considered only as reaction intermediates. Four-membered lactones (β-lactones from β-hydroxycarboxylic acids) are known, but special methods are required to prepare them [1], [2]. The exceptional reactivity of these compounds is a consequence of their highly strained rings. For example, they react with ammonia to form amides of the corresponding hydroxycarboxylic acids, which are subject to further conversion to amino acids.

Because of the properties described above, the hydroxyl group of a hydroxycarboxylic acid can be converted into various derivatives. Thus, treatment of lactic acid with hydrogen bromide results in α-bromopropionic acid. Hydrogen iodide can be used to reduce a hydroxycarboxylic acid to the corresponding unsubstituted acid, which is particularly easy with acids from the sugar family.

Saccharic acid lactones are converted easily to polyhydroxyaldehydes (aldoses).

Phosphorus pentachloride leads to replacement of the hydroxyl group in a hydroxycarboxylic acid by chlorine, with the carboxyl group simultaneously converted into an acid chloride moiety. Treatment with *thionyl chloride* results in an unstable sulfurous ester of the acid chloride, which will react, with an alcohol to give a hydroxyester or with ammonia to yield a hydroxyamide. If the hydroxyl group is protected by acetylation, thionyl chloride treatment leads only to the corresponding acid chloride.

3. Preparation

In addition to their isolation from natural sources, hydroxycarboxylic acids can also be obtained by a number of synthetic routes. One general approach involves hydrolysis of a halocarboxylic acid:

This route is in most cases quite straightforward for the preparation of α-hydroxycarboxylic acids (e.g., glycolic acid), but β- and γ-halocarboxylic acids lead instead to the corresponding lactones.

Certain hydroxycarboxylic acids may also be prepared by acid- or base-catalyzed hydration of an unsaturated carboxylic acid.

For example, either maleic or fumaric acid can serve as a source of racemic tartaric acid, and acrylic acid can be converted in this way to β-hydroxypropionic acid (hydracrylic acid).

α-Hydroxycarboxylic acids may be prepared by the action of zinc and an alkyl iodide on an oxalate ester. Cyanohydrin synthesis is another synthetic route to α-hydroxycarboxylic acids, one example being the synthesis of (*R,S*)-lactic acid from acetaldehyde via lactonitrile:

Another interesting preparative method involves diazotization as a means of deaminating an amino acid:

α-Olefins react with liquid dinitrogen tetroxide at 15 – 20 °C to produce nitrate esters of α-hydroxycarboxylic acids, compounds whose electrochemical reactivity is described in [3].

β-Hydroxycarboxylic acids can be prepared from epoxides by treatment with hydrogencyanide, followed by hydrolysis of the intermediate nitriles:

An alternative is the Kolbe nitrile synthesis involving addition of hypochlorous acid to an olefin. This results initially in a chlorohydrin, which can be converted with cyanide ion to a hydroxynitrile, which is then hydrolyzed:

β-Hydroxycarboxylic acids can also be prepared from α-halocarboxylic acid esters by Reformatsky reaction with an aldehyde or ketone in the presence of activated zinc [4]. Another approach utilizes β-lactones, which are readily accessible through ketene treatment of aldehydes or ketones [5]. Thus, acetaldehyde reacts with ketene in the presence of zinc salts to give β-butyrolactone. Finally, esters of β-ketoacids are subject to catalytic hydrogenation, a method that is also applicable to the synthesis of γ- and δ-hydroxycarboxylic acids from the corresponding γ- and δ-ketoesters.

For example, catalytic hydrogenation of acetoacetic esters give the esters of (*R,S*)-β-hydroxybutyric acid.

Both γ- and *δ-hydroxycarboxylic acids* can be prepared by alkaline hydrolysis of the corresponding halo acids. In this case, the products are normally isolated in the form of alkali-metal salts.

Dihydroxycarboxylic acids may be made by reaction of unsaturated fatty acids (e.g., oleic acid) with hydrogen peroxide or peracid, in which epoxides are formed as intermediates. *Polyhydroxy acids* are also commonly prepared from unsaturated carboxylic acids, usually by permanganate oxidation.

Many of the methods described above lend themselves equally well to the synthesis of *polybasic hydroxycarboxylic acids.* For instance, *tartronic acid* has been prepared both by hydrolysis of monobromomalonic acid or by sodium amalgam reduction of mesoxalic acid (ketomalonic acid):

Another approach starts with glycerol, which upon oxidation with potassium permanganate yields tartronic acid, whereas treatment with nitric acid yields glyceric acid.

As in this case, careful selection of oxidizing agent often enables various hydroxycarboxylic acids to be obtained by starting with the same precursor, a point well illustrated by the oxidation of sugars (aldoses and ketoses). Mild oxidizing agents such as aqueous bromine or dilute nitric acid attack only the aldehyde functions of

aldoses (→ Carbohydrates), producing glyconic acids (e.g., gluconic acid from glucose). Such glyconic acids (also called "onic acids") are stable only in alkaline solution, where they exist as alkali-metal salts. The free acids rapidly cyclize to γ- or δ-lactones, with the γ-lactones preferred.

More powerful oxidizing agents such as concentrated nitric acid result in polyhydroxy dibasic acids (saccharic acids), which immediately cyclize to lactones. Thus, glucose leads to glucaric acid; mannose to mannaric acid; and galactose to mucic acid (galactaric acid). Even more vigorous oxidation causes cleavage of the carbon chain, yielding lower hydroxydicarboxylic acids.

Numerous branched and unbranched hydroxycarboxylic acids may be prepared by cleavage or oxidation (with alkaline permanganate, chromic acid, dilute nitric acid, or concentrated nitric acid) of a variety of starting materials [6–9]. Enzymatic production by fermentation is becoming increasingly important.

4. Analysis

The literature describes an array of color reactions for *qualitative determination* of hydroxycarboxylic acids. These include the yellow color obtained in the presence of iron(II) chloride, characteristic complexation phenomena with copper salts, and the distinctive color produced with ammonium vanadate. Nevertheless, none of these reactions can be regarded as truly specific.

The most satisfactory approach to *quantitative analysis* involves acidimetric titration of carboxyl groups. Because of the nearly universal tendency to lactone formation in equilibrium with the free acid, free and total acids must be determined separately. Thus, lactones are treated in the same way as other esters: Hydrolysis with excess NaOH is followed by back titration with acid. Other recommended methods for quantitative analysis rely on acetylation of hydroxyl groups or esterification of carboxyl groups, with subsequent determination of the resulting water.

Instrumental methods of analysis are playing an increasingly important role, including IR, NMR and MS spectroscopy and, especially, chromatography (e.g., thin-layer chromatography and HPLC). Nevertheless, such methods prove reliable only if they are carefully adapted to suit the specific problem. A typical procedure involves methylation or silylation, followed by identification and quantification with GC – MS [7].

5. Specific Aliphatic Hydroxycarboxylic Acids of Commercial Significance

5.1. Glycolic Acid (Hydroxyacetic Acid, 2-Hydroxyethanoic Acid) [10]

The chemical structure, molecular mass, and CAS registry number of glycolic acid are given in Table 1. Its physical properties are listed in Table 2 and in the following material:

mp:	
α-Modification	78 – 80 °C
β-Modification, metastable	63 °C
Heat of combustion	−697.23 kJ/mol
Heat of solution in water (infinite dilution)	−11.71 kJ/mol
Dissociation constant (at 25 °C)	1.54×10^{-4}
pH (1 M solution)	2.4

Solid glycolic acid forms colorless, monoclinic, prismatic crystals. The acid is freely soluble in water, methanol, ethanol, acetone, and

ethyl acetate. Glycolic acid is only slightly steam volatile and cannot be destilled under vacuum; attempts result in self-esterification with loss of water, leading to di- and polyglycolides. However, newer results show that glycolic acid can be vaporized without decomposition. In the vapor phase it can be dehydrogenated catalytically to glyoxylic acid [11].

5.1.1. Preparation

Glycolic acid is usually produced by hydrolysis of molten monochloroacetic acid with 50 % aqueous sodium hydroxide at 90 – 130 °C. The resulting glycolic acid solution has a concentration of ca. 60 % and contains 12 – 14 % sodium chloride. The salt may be removed by evaporative concentration, followed by extraction of the acid with acetone [12]. Attempts have also been made to conduct the hydrolysis with acid catalysts at 150 – 200 °C with water or steam under pressure [13]. In this case, the byproduct is hydrogen chloride, rather than sodium chloride, which can be removed by distillation. The principal disadvantage of the method is the need for relatively large volumes of water.

Glycolic acid is produced commercially in the United States (Du Pont) by treating formaldehyde or trioxymethylene with carbon monoxide and water in the presence of acid catalysts at >30 MPa [14]. Another process, previously utilized by Degussa, involves electrolytic reduction of oxalic acid [15]. The compound can also be prepared in 90 % yield by hydrolysis of the corresponding nitrile, obtained by reaction of formaldehyde with hydrocyanic acid [16].

5.1.2. Uses

Glycolic acid is available commercially as either a 57 % (Hoechst) or a 70 % (Du Pont) aqueous solution. Total annual consumption worldwide is ca. 2000 – 3000 t of solution.

Glycolic acid is used in textile dyeing, printing, and creaseproofing. The fact that it can form a chelate with calcium(II) ions makes it well-suited to hide deliming in the leather industry, as well as to inclusion in alum and chrome mordants and in fur-processing operations. The compound has little tendency to cause corrosion, and this characteristic, coupled with its bactericidal properties, makes it suitable for incorporation into acidic cleansing agents. It is especially well-adapted to cleansing operations involving milk containers, milk-processing equipment, and drinking fountains, as well as rust and scale removal in heat exchangers and pipelines. Glycolic acid inhibits the growth of iron-oxidizing bacteria. The use of glycolic acid eliminates the need for simultaneous addition of chelating agents and bactericides. The effectiveness of glycolic acid as a complexing agent also contributes to its use in copper polishes, as an etching agent for lithographic plates, and in the preparation of electropolishing and galvanizing baths.

Safety Considerations. According to section 1.4 of the hazardous materials regulation, Gef Stoff V (Federal Republic of Germany), and to the EEC guidelines, glycolic acid solutions are "corrosive."

Analysis. Glycolic acid may be detected qualitatively by the violet color formed with 2,7-dihydroxynaphthalene [17]. The preferred method of quantitative analysis (in the absence of other acidic or hydrolyzable substances) is acidimetric titration. Because of the tendency of lactide formation free and total acid must be determined separately.

5.1.3. Derivatives

The glycolic acid esters *methyl glycolate* [*96-35-5*], *bp* 147 – 149 °C, and *ethyl glycolate* [*623-50-7*], *bp* 158 – 159 °C, both serve as starting materials for the laboratory preparation of pure glycolic acid [18] and were formerly employed as solvents for resins and for nitro- or acetyl cellulose. Apart from these two materials, only carboxymethyl cellulose [*9004-32-4*], (→ Cellulose Ethers, Chap. 6. and *n*-butyl glycolate have commercial significance.

***n*-Butyl Glycolate** (see Table 1).

Physical Properties. *n*-Butyl glycolate is a colorless liquid, which is miscible with most organic solvents. Its physical properties are summarized in Table 2. The solubility in water is limited to 8 wt % (20 °C), although the compound itself may contain up to 25 wt % water.

Production. *n*-Butyl glycolate is produced by treatment of sodium chloroacetate with *n*-butyl alcohol at 125 – 160 °C, followed by vacuum distillation [19].

Applications. *n*-Butyl glycolate is used primarily as a varnish additive, valued because of its low volatility. Trade names include Polysolvan-O (Hoechst) and GB-Ester (Wacker). It confers smooth spreading properties and high gloss on nitrocellulose varnish. For acetyl cellulose, it is effective as a blush inhibitor under conditions of high humidity. Due to its good blending properties, *n*-butyl glycolate is also used as an additive in alkyd resins and oil-based paints.

Safety Considerations. *n*-Butyl glycolate is not regarded as hazardous.

5.2. Hydroxypropionic Acids and β-Propiolactone

Of the two isomeric hydroxypropionic acids, only α-hydroxypropionic acid (→ Lactic Acid) is optically active.

β-Hydroxypropionic Acid (Hydracrylic Acid, 3-Hydroxypropanoic Acid) [20] (see Table 1).

Physical Properties. The most important physical properties of β-hydroxypropionic acid are listed in Table 2); its dissociation constant at 25 °C is 3.11×10^{-5}. β-Hydroxypropionic acid forms a highly acidic syrup, which loses water upon heating.

Preparation. β-Hydroxypropionic acid can be prepared by alkaline hydration of acrylic acid or by treatment of ethylene chlorohydrin with sodium cyanide, followed by hydrolysis of the resulting β-hydroxypropionitrile. It is also readily obtained by hydrolysis of the commercially important and easily accessible compound β-propiolactone.

β-Propiolactone (Oxetan-2-One) [21] (see Table 1).

Physical Properties [1]. The physical properties of β-propiolactone are summarized in Table 2 and in the following material:

Standard heat of formation	−330.0 kJ/mol
Standard heat of combustion	−1422.0 kJ/mol

β-Propiolactone is a colorless, highly reactive liquid, that is soluble in water, alcohol, acetone, and chloroform (solubility in water at 25 °C, 37 vol %).

Chemical Properties. β-Propiolactone reacts with alcohols, acid chlorides, ammonia, and water to yield β-substituted propionic acid derivatives. The most important characteristic of the substance is its ability to polymerize. This highly exothermic process occurs simply by warming, although it is also catalyzed by both acid and base.

Preparation. β-Propiolactone is synthesized by passing equimolar amounts of ketene and formaldehyde into either acetone or β-propiolactone itself. The reaction is carried out at low temperature (<20 °C) with a yield of ca. 90 % [5]. Both aluminum chloride and zinc chloride have been employed as catalysts, and the use of methyl borate has also been suggested.

Applications. As late as 1974, β-propiolactone was used in the United States in the preparation of acrylic acid and acrylate esters [22]. Today, its principal significance is as a reactive intermediate in organic syntheses; a small amount is treated with ammonia to provide β-alanine. β-Propiolactone was also used as a disinfectant. It appeared to be an attractive replacement for formaldehyde due to its 25-fold greater disinfecting power, but it has since been abandoned because of its carcinogenic properties.

Safety Considerations. In the EEC hazardous materials guideline and in the Gef Stoff V (Federal Republic of Germany) β-propiolactone is classed as a strong carcinogen and is considered extremely dangerous at concentrations $\geq$1 wt %.

5.3. Hydroxybutyric Acids

Of the three structural isomers α-, β-, and γ-hydroxybutyric acid, only the α- and β-acids are optically active. Racemic mixtures of each can be separated into optical antipodes by way of the corresponding strychnine or brucine salts.

All three acids are soluble in water, ethanol, diethyl ether, and numerous organic solvents, and decompose readily on dry distillation. β-Hydroxybutyric acid easily loses water to give crotonic acid, and γ-hydroxybutyric acid is transformed even at low temperature to γ-butyrolactone.

(*R,S*-)-α-Hydroxybutyric Acid [(*R,S*-)-2-Hydroxybutanoic Acid] [23], (see Table 1). The physical properties of (*R,S*)-α-hydroxybutyric acid are listed in Table 2.

Preparation. (*R,S*)-α-Hydroxybutyric acid results as main product from treating butyraldehyde with alkaline sodium hypochlorite solution or from heating α-bromobutyric acid with formamide at 150 °C.

(*R,S*-)-β-Hydroxybutyric Acid [(*R,S*-)-3-Hydroxybutanoic Acid] [24], (see Table 1). *Physical Properties.* The *mp* of racemic β-hydroxybutyric acid is 48 – 50 °C; it is commonly described in the literature as a syrupy liquid (see Table 2). Pure (*R*)-(−)-β-hydroxybutyric acid [*625-72-9*] is a solid with *mp* 49 – 50 °C.

Preparation. (*R,S*)-β-Hydroxybutyric acid results from hydrolysis of β-butyrolactone, which in turn can be produced by the addition of ketene to acetaldehyde in the presence of boron trifluoride or zinc salts [5]. The compound is also prepared by reduction of acetoacetic acid with sodium amalgam in alkaline solution.

γ-Hydroxybutyric Acid (4-Hydroxybutanoic Acid) [25] (see Table 1).

Physical Properties. The most important physical properties of γ-hydroxybutyric acid are listed in Table 2. The dissociation constant at 25 °C is 1.93×10^{-5}. At ambient temperature, the acid is a liquid and consists in part of lactone.

Preparation. γ-Hydroxybutyric acid is obtained from γ-butyrolactone by alkaline hydrolysis and isolated as the alkali-metal salt. γ-Butyrolactone is produced by dehydrocyclization of 1,4-butanediol.

Applications. Hydroxybutyric acids were utilized in the manufacture of plasticizers, but their current applications are quite limited. The related lactones are some times used as starting materials or intermediates in organic synthesis.

Optically active *β-hydroxybutyric acid* is an important pharmacological agent [26]. Biodegradable *poly*(−(*R*)-(−)-*β-hydroxybutyric acids* (named PHB) have been used in the context of controlled long-term parenteral application of drugs through implantation. These materials offer a number of advantages relative to other implantation polymers [e.g., poly(methacrylic acid) derivatives, poly(glycolic acid), poly(lactic acid)] [27]. Poly(β-hydroxybutyric acid) has also been considered as a potential textile material.

γ-Hydroxybutyric acid has been used as an anesthetic and pain killer. It has a stabilizing effect on blood pressure and induces a state of unconsciousness, characteristics that have encouraged its application especially in geriatrics [28].

5.4. (*R,S*)-Malic Acid [(*R,S*)-Hydroxysuccinic Acid, (*R,S*)-Hydroxybutanedioic Acid] [29], [30](see Table 1.)

Physical Properties (see Table 2). Malic acid is a colorless, odorless, crystalline substance. It is highly soluble in water (100 g of water dissolves 126.3 g of malic acid at 20 °C), methanol, ethanol, acetone, ether, and other polar solvents. Because it is a dibasic acid, it has two dissociation constants: at 20 °C, $K_{A_1} = 3.9\times10^{-4}$ and $K_{A_2} = 1.4\times10^{-5}$.

Preparation. (*R,S*)-Malic acid is prepared commercially in the United States and Canada by hydration of maleic anhydride (→ Maleic and Fumaric Acids) [31]. The sole manufacturer in the United States is Alberta Gas, with an annual capacity of ca. 5000 t. In this process maleic acid is heated at ca. 180 °C (under a pressure of ca. 1 MPa), malic acid is yielded as the main product. Byproducts are maleic and fumaric acids. The latter can be separated by filtration and returned to the process stream because of its low water solubility.

The filtrate is then concentrated; this causes separation of the malic acid, which is purified by multiple washings, evaporation, and recrystallization until the contents of fumaric and maleic

acids are reduced to 7.5 and <500 ppm, respectively. Additional purification is required to prepare pharmacological-grade material [32], [33].

Applications. (*R,S*)-Malic acid closely resembles both citric and tartaric acids in its physical and chemical properties. However, the compound has a more neutral flavor, so it is often preferred when the flavor of citric acid is considered objectionable. Examples include the impregnation of packing material for foodstuffs such as cheese or the acidification required during preparation of baked goods. It is widely used in the food industry as an acidulant and, to a lesser degree, as an acidity regulator. Relative to citric or tartaric acid, the flavor imparted by malic acid is not only more neutral but also of longer duration. Thus, citric acid imparts a strongly acidic taste to the tongue almost immediately, but the effect is brief. With malic acid, the sensation is less intense, but it lasts longer and is more consistent. Soft-drink manufacturers have discovered that this property helps mask the aftertaste associated with certain nonnutritive sweeteners and leads to a more balanced flavor profile. Moreover, synergistic effects are observed between these sweeteners and malic acid, which permit reductions of up to 20 % in the amount of sweetener required and 10 % in malic acid. Consequently, significant economic benefits may be realized. The economic picture is also influenced favorably by the fact that malic acid is available as an anhydrous powder.

Malic acid is used primarily as an ingredient in hard candys and other sweets, jams, jellies, and various canned fruits and vegetables. Most countries authorize its use as an additive in foodstuffs.

(*R*)-(+) *-Malic acid* [*636-61-3*] *and* (*S*)-(−)-*malic acid* [*97-67-6*] are isolated from natural sources by resolution of (*R,S*)-malic acid with the aid of an optically active base. (*S*)-(−)-Malic acid is also available through microbiological fermentation of fumaric acid [33]. The levorotatory *S*-enantiomer is widely distributed in fruit and displays the following characteristics that differ from those of the racemate: *mp*, 100 °C; d_4^{20}, 1.595; α_D^{18}, −2.3° (7 wt % in H_2O). The compound is soluble to the extent of 36.4 g in 100 g of water at 20 °C.

6. Toxicology

As previously noted, most important aliphatic hydroxycarboxylic acids occur as natural products. Because they serve as intermediates in plant and animal metabolic pathways, they do not exhibit many exceptionally toxic properties. Thus, only a few compounds listed in Table 1 are included in the *Register of Toxic Effects of Chemical Substances* prepared by NIOSH [35]. Certain hydroxycarboxylic acids (e.g., lactic, malic, tartaric, and citric) are even accepted as food additives or preservatives in most countries.

The following toxicity data for *citric acid* are taken from the NIOSH list [35, p. 945]:

LD_{50} (oral, rat)	11 700 mg/kg
LD_{50} (oral, mouse)	5 040 mg/kg
LD_{50} (oral, rabbit)	7 000 mg/kg

Glycolic acid was also permitted as a food preservative but later came to be considered suspect [36]. Today, it is described as moderately toxic, with the following data [35, p. 386],

LD_{50} (oral, rat)	950 mg/kg
LD_{50} (oral, guinea pig)	920 mg/kg

A derivative of glycolic acid *n-butyl glycolate* is described as displaying narcotic properties. It is also an irritant to both skin and mucous membranes. Nevertheless, it is markedly less toxic than glycolic acid, having an LD_{50} (oral, rat) of 4595 mg/kg.

The lowest reported lethal dose for *β-hydroxypropionic acid (hydracrylic acid)* derives from intravenous injection into rats: LD_{50} (i.v., rat) = 50 mg/kg [35, p. 447].

A derivative of β-hydroxypropionic acid *β-propiolactone* is of considerable interest because of its viricidal and bactericidal properties, and was used medically in sterilization and disinfection. Nevertheless, it has since been found to be a mutagen [37]. Animal studies have provided incontrovertible evidence that the compound displays carcinogenic properties irrespective of whether it is delivered orally, topically on the skin, or by intravenous, intraperitoneal, or subcutaneous injection [38], [35, p. 1326]. β-Propiolactone is a powerful irritant to the skin and eyes. The following toxicity data have been reported:

LC_{50} (inhalation, rat)	25 ppm, 6 h
LD_{50} (i.v., mouse)	345 mg/kg

Because of its cytotoxic properties, β-propiolactone has been added to Category A 2 of the official list of carcinogenic materials [39].

By contrast, *γ-butyrolactone* is completely free of these cytotoxic characteristics. Despite numerous animal studies, no evidence has been obtained to suggest carcinogenicity. Nonetheless, the compound is moderately toxic, having an LD_{50} (oral, rat) of 1800 mg/kg [35, p. 946]. The narcotic effects observed when γ-butyrolactone is administered orally or intraperitoneally have been ascribed to γ-hydroxybutyric acid, from which it is derived.

From animal studies, the sodium salt of γ-hydroxybutyric acid is known to possess narcotic properties [40]. A dose of ca. 40 mg/kg leads to nearly natural sleep in humans, with essentially no side effects.

1. Introduction

Aromatic hydroxycarboxylic acids (i.e., hydroxycarboxylic acids with phenolic hydroxyl groups) occur widely in nature in the form of their esters, ethers, intermolecular esters (depsides), or cyclic ether – esters (depsidones). Structural formulas of the most important depsides and of depsidone are given below:

m-Digallic acid
[*536-08-3*]

m-Trigallic acid
[*2131-66-0*]

Depsidone
[*3580-77-6*]

Hydrolyzable tanning agents such as tannin (ester of gallic acid, tannic acid) [*5424-20*] are esters of aromatic hydroxycarboxylic acids with polyhydric alcohols and sugars. Aromatic hydroxycarboxylic acids are used mainly for pharmaceutical and cosmetic purposes: as disinfectants, preservatives, emulsifiers, analgesics, and antirheumatic and antipyretic drugs. Their use in the production of dyes and plastics is increasingly important, especially in color developing, and in liquid crystal polymers (→Liquid Crystals).

2. General Properties

Monohydroxybenzoic acids are dibasic acids. Thus, one mole of alkali forms the carboxylate and a second mole converts the phenolic hydroxyl group into a phenolate. The acidity of each group depends on its relative position (see Table 1). The carboxyl and hydroxyl group acidities of 3- and 4-hydroxybenzoic acids are comparable to those of benzoic acid and phenol. However, the corresponding acidities of 2-hydroxybenzoic acid (salicylic acid [*69-72-7*]) are different. The higher acidity of the carboxylate group in this case is the result of intramolecular chelate formation.

Table 1. Dependence of dissociation constants for aromatic hydroxycarboxylic acids on relative position of hydroxyl and carboxyl groups

		K_1(−COOH), $\times 10^{-5}$	K_2(−OH), $\times 10^{-10}$

This accounts for its high steam volatility and ease of sublimation. 2-Hydroxy- and 4-hydroxybenzoic acids decarboxylate above their melting point; 2,4- and 2,6-dihydroxybenzoic acids decarboxylate even when heated in an aqueous solution. This process is catalyzed by strong acid. The carboxyl group is esterified with alcohols under acid catalysis without detectable etherization of the phenolic hydroxyl group. Ether – esters can be obtained easily from the dialkali salts by using alkyl halides or dialkyl sulfates. Alkaline hydrolysis of ether – esters produces alkoxycarboxylic acids. Electrophilic substitution (e.g., nitration, sulfonation, chlorination) leads to attack of the aromatic nucleus at the 2- or 4-position, with the 4-position preferred.

Analysis. Methods of analyzing carboxylic acids and phenols are also applicable to hydroxycarboxylic acids. In practice, alkalimetric titration (in special cases, potentiometric titration) is used. With potentiometric determination of the equivalence point, the hydroxyl group can also be determined. Trace analyses are carried out by colorimetric methods with iron(III) chloride [4]. Thin-layer chromatography is a suitable method for checking purity. Here, individual acids are made visible by means of alkaline (Na_2CO_3) coupling with diazotized 4-nitroaniline, by spraying with iron(III) chloride, or by fluorescence in UV light. For quantitative analysis, HPLC methods are suitable. Alternatively, the components can be derivatized and capillary gas chromatographic methods used to separate them [5].

3. Production

Kolbe – Schmitt or Marassé Carboxylation. Yields according to the Kolbe reaction of solid anhydrous alkali phenolates in a stream of carbon dioxide were improved by SCHMITT who carried out the reaction under pressure [6]. The Marassé method involves the conversion of phenol with potassium carbonate and does not work with less expensive sodium carbonate [7]. The Kolbe – Schmitt synthesis is a gas-solid reaction; thus the phenolate must be present as a fine powder rather than a melt to achieve better contact. For the same reason, inert high boilers, such as higher alkanes, are used for thorough mixing [8]. The alkali phenolates are converted into alkali-metal salts of the corresponding hydroxycarboxylic acids, generally by stirring, in pressurized vessels at 120 – 180 °C and a carbon dioxide pressure of 0.5 MPa. Conditions up to 260 °C and 120 MPa are required in the presence of electron-withdrawing groups or in the case of sterically hindered phenols. 3-Nitrophenol [*555-84-7*] is carboxylated with a yield of only 19 % [9]. Carboxylation occurs easily when the aromatic compounds are activated by electron-donating substituents, as in the case of aminophenols or di- and trihydroxyaromatic compounds. Reaction then occurs even in an aqueous alkali-metal carbonate solution.

The yield of dicarboxylic acid increases with increasing temperature and pressure above 1.0 MPa. At 10.0 MPa and 220 °C the equilibrium is shifted mainly toward the product [10]. The type of alkali metal is important for the course of the reaction. Sodium and lithium phenolates are carboxylated at medium temperature (150 – 180 °C) to form mainly 2-hydroxycarboxylic acids. Potassium phenolates give 2 – 4 mixtures at medium temperature, but above 220 °C the 4-hydroxycarboxylic acid is favored.

Exchange of a Sulfonic Acid, a Halide, or a Diazonium Group for the Hydroxyl Group. The most common method for producing 3-hydroxybenzoic acid [*99-06-9*] involves the alkali melt of *3-sulfobenzoic acid* [*121-53-9*] [11]. In some cases, if the carboxyl group is activated by electron-donating substituents, decarboxylation takes place during melting. Nucleophilic substitution of *halogen* by the hydroxyl group is particularly effective if the halogen atom is activated by electron-withdrawing groups in the *ortho* or *para* position [12]. The conversion of *aminobenzoic acids* into hydroxycarboxylic acids is possible via the diazonium salt [13].

Hydroxycarboxylic Acids via Oxidation. Oxidation of *alkylphenols* is another method of producing aromatic hydroxycarboxylic acids. In general the phenolic hydroxyl group must be

protected (e.g., by esterification with sulfuric acid). The alkyl moiety of the sulfuric acid ester is then oxidized easily by using potassium permanganate or chromic acid [14]. Aromatic hydroxycarboxylic acids can also be produced by oxidative alkali melt of appropriately substituted phenols. Alkyl groups ortho to the phenolic hydroxyl group are oxidized most easily [15]. The oxidative alkali melt of *aromatic hydroxyaldehydes* gives the corresponding hydroxycarboxylic acids in good yield [16]. In the presence of silver catalysts, oxidation is possible even in aqueous alkali solution [17]. *Hydroxyacetophenones* can be converted into hydroxycarboxylic acids by using iodine in pyridine (haloform reaction), followed by alkaline hydrolysis of the intermediate pyridinium iodide [18].

Direct introduction of a *hydroxyl* group into the aromatic nucleus by oxidation is possible in the case of ammonium benzoates by using hydrogen peroxide [19]. Thus, the first stage of the Dow process (production of phenols from benzoic acids) involves hydroxylation by air of the metal benzoate ortho to the carboxyl group [20].

Introduction of a *carboxyl group* is achieved by reaction of phenols with tetrachloromethane in the presence of alkali and powdered copper or copper salts [21]. Alkyl ethers of hydroxycarboxylic acids can be obtained directly by carboxylation of alkoxyphenyl metal halides (e.g., magnesium or lithium compounds) with carbon dioxide. Amides and thioamides of alkoxycarboxylic acids are formed by conversion of phenol ethers with carbamoyl chlorides, isocyanates, or isothiocyanates in the presence of aluminum chloride [22]. Rearrangement of arylurethanes in the presence of Lewis acids (e.g., aluminum chloride) may give good yields of the amides of the corresponding hydroxycarboxylic acids [23].

4. Individual Aromatic Hydroxycarboxylic Acids

4.1. Monohydroxycarboxylic Acids

4.1.1. 3-Hydroxybenzoic Acid

Physical Properties. 3-Hydroxybenzoic acid [*99-06-9*], $C_7H_6O_3$, M_r 138.12, crystallizes as white needles (from water) or rhombic prisms (from alcohol). Important physical properties follow: *mp* 203 °C; d_{25} 1.473; dissociation constants K_1 8.71×10^{-5}, K_2 1.18×10^{-10} (at 19 °C); solubility (in 100 g of solution): water 6.11 g (69 °C), 98 % ethanol 39.6 g (65 °C), and *n*-butanol 20.7 g (36.5 °C).

Chemical Properties. 3-Hydroxybenzoic acid does not undergo decarboxylation at elevated temperature and is stable up to 300 °C. This is in contrast to 2- and 4-hydroxybenzoic acids. Electrophilic substitution (e.g., nitration, halogenation, sulfonation) occurs *ortho* or *para* to the hydroxyl group. Thus, nitration with 62 % aqueous nitric acid gives 2-nitro-3-hydroxybenzoic acid as the main product, along with 4-nitro- and 6-nitro-3-hydroxybenzoic acids [24].

Production. 3-Hydroxybenzoic acid can be obtained by alkali melt of the sodium salt of 3-sulfobenzoic acid at 210 – 220 °C. The crude acid precipitates on acidification. It can be purified by recrystallization from water with the addition of activated carbon [11]. 3-Hydroxybenzoic acid can also be obtained from 3-nitrobenzoic acid esters. This occurs via catalytic hydrogenation followed by diazotization of the aminobenzoic acid ester formed. The diazonium salt is then heated [25] with aqueous sulfuric acid. Another production method is oxidation of 3-hydroxybenzaldehyde [*100-83-4*] by bubbling air through a hot aqueous sodium hydroxide suspension [26].

Uses. 3-Hydroxybenzoic acid is used as an intermediate in the manufacture of pharmaceuticals and pesticides. The 3-hydroxybenzoic acid ester of tropine is used in ophthalmology to dilate the pupils. The sodium salt of 3-hydroxybenzoic acid is a cholepoietic agent. Esters and metal salts have germicidal and preservative properties, and are used in food preservation. Ether – esters are suitable as plasticizers for vinyl and cellulose resins.

4.1.2. 4-Hydroxybenzoic Acid

Physical Properties. 4-Hydroxybenzoic acid [*99-96-7*] $C_7H_6O_3$, M_r 138.12, is a white granular crystalline powder consisting of mono-

Table 2. Properties of 4-hydroxybenzoic acid esters

clinic prisms. The physical properties are summarized here: *mp* 216.3 °C; d_{20} 1.497; dissociation constants K_1 3.3×10^{-5}, K_2 4.8×10^{-10} (19 °C); solubility (in 100 g of solution): water 0.49 g (20 °C), 33.5 g (100 °C); 99 % ethanol 38.75 g (67 °C); and *n*-butanol 19.5 g (32.5 °C). 4-Hydroxybenzoic acid is sparingly soluble in chloroform.

Table 2 lists properties of the most commonly used esters.

Chemical Properties. Above 200 °C, 4-hydroxybenzoic acid undergoes decarboxylation to produce phenol and carbon dioxide. Electrophilic substitution (e.g., nitration, sulfonation, or halogenation) occurs *ortho* to the hydroxyl group. With iron(III) chloride, no color reaction occurs but a yellow precipitate is formed.

Production. 4-Hydroxybenzoic acid is produced by carboxylation of potassium phenolate above 220 °C and with a carbon dioxide pressure of 0.45 MPa. The yield of 4-hydroxybenzoic acid (partly present as the dipotassium salt) is 80 % of the theoretical amount in which the conversion of phenolate is 60 %. 4-Hydroxybenzoic acid can also be obtained by isomerization of dipotassium salicylate [27] at temperatures up to 240 °C and under carbon dioxide pressure (slightly above atmospheric pressure) [28], or by oxidation of the alkali-metal salt of *p*-cresol [*106-44-5*] on metal oxides at 260 – 270 °C [29]. Reaction of phenol with tetrachloromethane [*56-23-5*] in the presence of alkali produces salicylic acid [*69-72-7*] as the main product and smaller amounts of 4-hydroxybenzoic acid [*99-96-7*] [21].

Uses. *4-Hydroxybenzoic acid* is an intermediate in the manufacture of dyes, pharmaceuticals, pesticides [30], and plastics. It is used as an emulsifier and also as a corrosion-protection agent [31]. Its esters and corresponding sodium salts are antimicrobial substances with a high no-effect level (1200 mg per kilogram of body weight) [32]. They are, therefore, used under weakly acidic to weakly basic conditions as food preservatives (e.g., in fruit juice), cosmetics, and pharmaceuticals, as well as in technical products (e.g., in lubricants, anti-freezing agents) [33]. Benzyl esters are relatively soluble in preparations containing sugar. Table 2 lists observed bacteriostatic effects [34] compared to phenol.

4-Hydroxybenzoic acid is also used in polymers as a component in the manufacture of polyester and as a constituent of *liquid crystal polymers* [35] (→ Liquid Crystals).

Esters. The food preservative " PHB-Ester" is a mixture of the ethyl and *n*-propyl esters of 4-hydroxybenzoic acid. According to the preservatives regulations in the different countries [*EEC guideline* 64/52 date: 5. 11. 63, 24th amendment 85/585 date: 20. 12. 85; *United States:* Food and Drug Administration, HHS, 21 CFR Ch.I, 4. 1. 86, § 172.145, § 184.1490, § 184.1670; *Federal Republic of Germany:* Verordnung über die Zulassung von Zusatzstoffen zu Lebensmitteln, date: 22. 12. 81 (BGBl.

I, p. 1625/33) 1. amendment date: 20. 12. 84 (BGBl. I, p. 1652)], PHB-Ester in the amount of 0.1 – 10 g/kg is allowed in the preservation of foodstuffs. In Europe, PHB-Esters are identified as E 214 – E 219, in the United States as heptylparaben, methylparaben and propylparaben. A mixture of 60 % ethyl and 40 % propyl ester is particularly effective. Use of such preservatives is, however, restricted by law in selected foodstuffs (e.g., wine) [36]. Some higher esters are used for termite control [37].

The PHB-Esters that are solids as pure components give eutectic mixtures which are liquid at room temperature and are used as oil-in-water emulsions (→ Emulsions) [38]. See Table 2.

4-Hydroxybenzoic acid esters, particularly PHB-benzyl ester, are also employed as color developers in pressure-sensitive [39] and thermosensitive [40] writing systems. Here, purification and decoloration of the PHB-Ester are achieved through distillation with the addition of sodium hydrogen sulfite [41].

4.1.3. Cresotic Acids

Of the ten isomeric cresotic acids, $C_8H_8O_3$, M_r 152.15, *o*- and *p*-cresotic acids are of most interest.

[83-40-9] [50-85-1] [89-56-5]

o-Cresotic acid [*83-40-9*] (2-hydroxy-3-toluic acid, 2-hydroxy-3-methylbenzoic acid), *mp* 165 °C, dissociation constant K_1 6.76×10^{-4}, is produced by carboxylation of the sodium salt of *o*-cresol [*95-48-7*] at 150 – 180 °C. The acid is sparingly soluble in water and has properties similar to salicylic acid. It is used as an intermediate in the preparation of pharmaceuticals and dyes. Its methyl ester is used as an aid in textile dyeing.

m-Cresotic Acid [*50-85-1*] (2-hydroxy-4-toluic acid, 2-hydroxy-4-methylbenzoic acid, 4-methylsalicylic acid), *mp* 177 °C, dissociation constant K_1 6.84×10^{-4}, is produced by carboxylation of the sodium salt of *m*-cresol [*108-39-4*]. It is used as an additive in galvanic baths [42].

p-Cresotic Acid [*89-56-5*] (2-hydroxy-5-methylbenzoic acid, *p*-homosalicylic acid), *mp* 153 °C, is produced by carboxylation of the sodium salt of *p*-cresol [*106-44-5*] with carbon dioxide at 150 – 180 °C. The acid is used as an intermediate in dye production.

4.2. Dihydroxybenzoic Acids

3,4-Dihydroxy- and 2,3-dihydroxybenzoic acids are both obtained by heating catechol [*120-80-9*] in aqueous ammonium carbonate solution at 140 °C.

99-50-3] [303-38-8] [89-86-1] [490-79-9]

3,4-Dihydroxybenzoic acid [*99-50-3*] (protocatechuic acid), $C_7H_6O_4$, M_r 154.1, *mp* 203 °C, undergoes decomposition to catechol [*120-80-9*] and carbon dioxide. The acid crystallizes as a monohydrate from aqueous solution.

The most important derivative of this acid is the monomethyl ether, *4-hydroxy-3-methoxybenzoic acid* [*121-34-6*] (vanillic acid), $C_8H_8O_4$, M_r 168.14, *mp* 211 °C (from water). It is obtained by careful alkali melt of vanillin [*121-33-5*] or oxidation of vanillin with silver oxide [43]. Vanillic acid and its esters are constituents of preservatives and disinfectants.

2,3-Dihydroxybenzoic acid [*303-38-8*], $C_7H_6O_4$, M_r 154.1, *mp* 206 °C, undergoes decomposition to catechol and carbon dioxide. The acid crystallizes from water as a dihydrate. Among other uses, it serves as an iron-complexing agent in drugs [44].

2,4-Dihydroxybenzoic acid [*89-86-1*] (*p*-hydroxysalicylic acid, β-resorcylic acid), $C_7H_6O_4$, M_r 154.1, *mp* 226 °C (decomp.), is sparingly soluble in water. The dissociation constant K_1 is 6.05×10^{-4} (30 °C). The acid is produced by conversion of resorcinol [*108-46-3*] with aqueous potassium carbonate solution at 100 °C and a carbon dioxide pressure of 0.45 MPa. In this case, 2,6-dihydroxybenzoic

acid [*303-07-1*] (γ-resorcylic acid) is formed as byproduct and can be separated by recrystallization [45]. Pure 2,4-dihydroxybenzoic acid can be produced by oxidation of 2,4-dihydroxyacetophenone [*89-84-9*] with iodine in pyridine [18].

2,4-Dihydroxybenzoic acid is used as an intermediate in the manufacture of dyes, pharmaceuticals and of additives in photography, and cosmetics. Dyes made from resorcylic acids differ from those made from salicylic acid in their deeper and more intense colors.

The acid is used to complex titanium(IV) fluoride [46], in the passivation of aluminum [47], and as an additive in drilling fluids [48].

3,5-Dihydroxybenzoic acid [*99-10-5*] (α-resorcylic acid), $C_7H_6O_4$, M_r 154.1, *mp* 237 °C (decomp.), is obtained by alkali melt of 3,5-disulfobenzoic acid [49].

2,5-Dihydroxybenzoic acid [*490-79-9*] (gentisic acid, 2,5-DHBA), $C_7H_6O_4$, M_r 154.1, *mp* 205 °C, is soluble in water and alcohols but insoluble in benzene and chloroform. The acid is stable in boiling water and gives a deep blue color with iron(III) chloride. Here, the acid decomposes to form *p*-benzoquinone [*106-51-4*] and carbon dioxide.

2,5-Dihydroxybenzoic acid is obtained by carboxylation of hydroquinone [*123-31-9*] with aqueous potassium hydrogen carbonate solution at 130 °C. It can also be made by oxidation of salicylic acid with potassium peroxodisulfate [*7727-21-7*] in the presence of iron sulfate [50]. 2,5-Dihydroxybenzoic acid is not obtained by reaction of carbon dioxide with the dialkali salt of hydroquinone: instead hydroquinone-2,5-dicarboxylic acid is formed.

2-5-Dihydroxybenzoic acid is used as an antirheumatic drug and, more recently, as a color developer for thermal paper [51].

4.3. Trihydroxybenzoic Acids

3,4,5-Trihydroxybenzoic Acid [*149-91-7*].

Physical Properties. 3,4,5-Trihydroxybenzoic acid (gallic acid), $C_7H_6O_5$, M_r 170.12, is a white to pale yellow crystalline powder, which crystallizes from water in the form of silky needles as the monohydrate (*mp* 258–263 °C) and undergoes decomposition to pyrogallol [*87-66-1*] and carbon dioxde: d_{25} 1.694, dissociation constants K_1 4.63×10^{-3} (at 30 °C) and K_2 1.41×10^{-9}. 3,4,5-Trihydroxybenzoic acid is soluble in warm water, ethanol, diethyl ether, and acetone but insoluble in benzene and chloroform.

Chemical Properties. Solutions of gallic acid, particularly of the alkali-metal salts, absorb oxygen and turn brown in air like pyrogallol. The acid is a strong reducing agent that can reduce gold or silver salts to the metal. With iron(III) salts, an intensive blue complex is formed that is used for ink dyes. Gallnut ink, which consists of gallic acid and iron(II) sulfate, produces the blue iron(III)–gallic acid complex on paper in air.

[*82-12-2*] [*476-66-4*]

When gallic acid is heated with concentrated sulfuric acid, hexahydroxyanthraquinone [*82-12-2*] (rufigallic acid) is produced by condensation. Reaction with *p*-nitrosodimethylaniline hydrogen chloride produces oxazine derivatives (→ Azine Dyes, Chap. 3.2., last paragraph). Oxidation with arsenic acid, permanganate, persulfate, or iodine yields ellagic acid [*476-66-4*], as does reaction of methyl gallate with iron(III) chloride. The carboxyl group undergoes azeotropic esterification with alcohols, or, by the Fischer method, with alcoholic hydrochloric acid. The ether–ester of gallic acid is obtained by conversion of dialkyl sulfates or alkyl halides in the presence of alkali, or by using diazomethane [*334-88-3*]. The hydroxyl group in the 4-position is the most reactive. 3,4,5-Trimethoxybenzoic acid [*118-41-2*] undergoes partial hydrolysis in strong acid to form 4-hydroxy-3,5-dimethoxybenzoic acid [*530-57-4*] (syringic acid).

Production. Gallic acid, a component of many tanning agents is an endogenous product in plants. The acid occurs free or bound to tannin [*1401-55-4*] (e.g., in divi-divi, oak bark, gallnuts, pomegranate roots, sumac, and tea). The acid is produced from tannin-rich aqueous gallnut extracts by acidic or alkaline hydrolysis. It

is also obtained by using the enzyme tannase [*9025-71-2*] or molds (*Penicillium glaucum, Aspergillus niger*) to cleave tannin by fermentation. Both the metabolism of gallic acid and its impact on plant growth enzymes have been studied [52].

Uses. Gallic acid is used for the manufacture of iron gallnut ink (see above) and as an intermediate in the production of dyes (e.g., anthragallol [*620-64-2*], gallocyanine [*1562-85-2*], galloflavin [*568-80-9*], and rufigallic acid [*82-12-2*]). Gallate esters, particularly methyl gallate [*99-24-1*] (gallicin), *mp* 157 °C, and propyl gallate [*121-79-9*], *mp* 150 °C, are used as antioxidants and food preservatives (e.g., for fats) [53]. Gallic acid is also employed as a reducing agent for pharmaceutical purposes (Dermatol, Airol, bismuth salt of gallic acid) [54] and for the production of photographic developers and pyrogallol.

4.4. Mandelic Acid

Racemic (*R,S*)-Mandelic Acid [*611-72-3*].

Physical Properties. (*R,S*)- Mandelic acid (α-hydroxyphenylacetic acid, phenylglycolic acid), $C_6H_5-CH(OH)-COOH$, $C_8H_8O_3$, M_r 152.15, *mp* 118 – 121 °C, is a colorless crystalline powder. It is readily soluble in ethanol and diethyl ether, less soluble in chloroform, and insoluble in petroleum ether. Its water solubility is 15 g per 100 mL of water. In alkaline solution, mandelic acid dissolves to form salts.

Chemical Properties. Mandelic acid turns brown when exposed to light. It can be esterified easily with alcohols in the presence of hydrogen chloride.

Production. (*R,S*)-mandelic acid is produced by hydrolysis of mandelic acid nitrile [*532-28-5*] (*mp* 10 °C) with hydrochloric acid. Mandelic acid nitrile is obtained by the conversion of benzaldehyde [*100-52-7*] and hydrogen cyanide in the nascent state (NaCN + HCl) under refrigeration. Another method of producing mandelic acid is the hydrolysis of α,α-dichloroacetophenone with alkali.

Uses. Mandelic acid esters have analgesic, antirheumatic, and spasmolytic effects. For examples, *cis*-3,5,5-trimethylcyclohexyl mandelate [*456-59-7*] (cyclandelate, Spasmocyclon, Clan-dilon), $C_{17}H_{24}O_3$, M_r 276.38, *mp* 54 – 58 °C, is used as a spasmolytic and to stimulate blood circulation. Mandelic acid tropine ester [*51-56-9*] (homatropine – HBr), $C_{16}H_{22}BrNO_3$, M_r 356.26, *mp* 212 – 215 °C, is readily soluble in water and ethanol, and is used in ophthalmology to dilate the pupils. Hexamethylenetetramine mandelate [*587-23-5*] (mandelamine, Mandropine, diuramine, hexydaline) $C_{14}H_{20}N_4O_3$, M_r 292.34, *mp* 127 – 130 °C, forms colorless crystals that are readily soluble in diethyl ether. This salt is used to treat urinary tract infections.

Levorotatory (*R*)(−)-Mandelic Acid [*611-71-2*]. (*R*)-Mandelic acid forms colorless crystals, *mp* 132 – 135 °C, specific rotation $[\alpha]_D^{20}$ ($c = 5$) −154 to 157 °C. It is produced by resolution of racemic (*R,S*)-mandelic acid with cinchonine [*118-10-5*] in aqueous solution, whereby the salt of (*S*)-(+)-mandelic acid crystallizes. If resolution is performed with *S*-(+)-aminodiol [*3306-06-7*], (*R*)-(−)-mandelic acid crystallizes, while (*S*)-(+)-mandelic acid [*17199-29-0*] remains in solution. (*R*)-(−)- and (*S*)-(+)-mandelic acid can again be subjected to racemic resolution after isomerization.

5. Toxicology

Toxicological and physiological properties of the different aromatic hydroxycarboxylic acids are summarized in the following material.

3-Hydroxybenzoic Acid. LD_{50} 3700 mg/kg (rat, i.p.), TDLo 400 mg/kg (rat, s.c., 11 d pregnant); classification: drug, teratogen [55, ; date: 1/84].

4-Hydroxybenzoic Acid. LD_{50} 2200 mg/kg (mouse, oral), LD_{50} 210 mg/kg (mouse, i.p.), LD_{50} 1050 mg/kg (mouse, s.c.); classification: drug, mutagen [55, ; date: 8/83].

o-Cresotic Acid. LD_{50} 1000 mg/kg (mouse, oral). LD_{50} 345 mg/kg (mouse, i.v.); classification: drug [55, ; date: 6/85].

m-Cresotic Acid. LD_{50} 1800 mg/kg (mouse, oral); classification: drug [55, ; date: 6/85].

p-Cresotic Acid. LD_{50} 1000 mg/kg (mouse, oral); classification: drug [55, ; date: 6/85].

4-Hydroxy-3-methoxybenzoic Acid. Classification: mutagen [55, ; date: 8/82].

2,4-Dihydroxybenzoic Acid. LDLo 642 mg/kg (rat, s.c., 11 d pregnant); classification: teratogen [55, ; date: 3/84].

3,5-Dihydroxybenzoic Acid. LD_{50} 2000 mg/kg (mouse, i.v.) [55, ; date: 6/84].

2,5-Dihydroxybenzoic Acid. 2,5 Dihydroxybenzoic acid is an intermediate in the metabolism of salicyclic acid [56]: LD_{50} 800 mg/kg (rat, oral) LD_{50} 3000 mg/kg (rat, i.p.), LD_{50} 374 mg/kg (mouse, i.v.), LDLo 380 mg/kg (rat, s.c., 9 d pregnant), LDLo 642 mg/kg (rat, s.c., 11 d pregant); classification: teratogen, natural product [55, ; date: 5/84].

3,4,5-Trihydroxybenzoic Acid. LD_{50} 320 mg/kg (mouse, i.v.), LD_{50} 5000 mg/kg (rabbit, oral), LDLo 800 mg/kg (mouse, i.p.), LDLo 5 mg/kg (mouse, s.c., 1 d pregnant); classification: agricultural chemical, mutagen, teratogen [55, ; date: 3/85].

1. Introduction

Hydroxylamine was first described in 1865 by LOSSEN [7], and the free base was isolated in 1891 by LOBRY DE BRUYN [8]. The first industrial process for production of hydroxylammonium sulfate was patented by RASCHIG [9] in Germany (1908) and in the United States (1911).

Salts of hydroxylamine and their solutions are of great industrial importance as intermediates, particularly in the production of caprolactam (→ Caprolactam). World capacity of hydroxylamine is estimated to be 800 000 t/a.

2. Physical Properties

Hydroxylamine [*7803-49-8*], NH_2OH, M_r 33.03, forms transparent, colorless, odorless crystals. The compound is readily soluble in water, methanol, and ethanol. Some physical properties of hydroxylamine are as follows:

mp	32.05 °C
bp (29 kPa)	56 °C
Vapor pressure	
at 0 °C	0.36 kPa
at 32 °C	7.1 kPa
Enthalpy of formation	−114 kJ/mol

2.1. Hydroxylammonium Sulfate

Crystalline hydroxylammonium sulfate [*10039-54-0*], $(NH_3OH)_2SO_4$ or $(NH_2OH)_2 \cdot H_2SO_4$, M_r164.14, is readily soluble in water but only slightly soluble in organic solvents. The density of the solid is 1.883 g/cm^3; the bulk density is ca. 1.10 g/cm^3. Hydroxylammonium sulfate decomposes above 120 °C. Aqueous solutions of hydroxylammonium sulfate are clear and colorless. The pH of a 1 wt % aqueous solution (20 °C) is 3.6. Some properties of hydroxylamine sulfate and its solutions are given in Table 1 [10].

Table 1. Properties of hydroxylammonium sulfate and its solutions

	Temperature, °C				
	20	40	60	80	100
Solubility (water), wt %	37.0	45.0	52.5	60.0	68.0
Density (aqueous solution), g/cm^3					
25 wt %	1.184	1.175	1.163		
Saturated	1.246	1.294	1.341	1.410	1.468
Dynamic viscosity (25 wt % aqueous solution), mPa · s	1.90	1.22	0.86	0.65	

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The specific heat of aqueous hydroxylammonium sulfate solutions in the range 20 – 80 °C is as follows:

Concentration, wt %	25	30	40
Specific heat, kJ kg^{-1} K^{-1}	3.426	3.338	3.087

2.2. Hydroxylammonium Chloride

Hydroxylammonium chloride [*5470-11-1*], $(NH_3OH)Cl$ or $NH_2OH \cdot HCl$, M_r 69.50, is a hygroscopic, crystalline salt that is readily soluble in water and in methanol. The addition of 0.5 wt % of pyrogenic silica hinders caking; the silica gel is insoluble and inert. Hydroxylammonium chloride has a density of 1.676 g/cm^3 and a bulk density of ca. 0.780 g/cm^3. It decomposes above 120 °C. The pH of a 1 wt % aqueous solution (20 °C) is 3.2. Some properties of hydroxylamine chloride and its solutions are given in Table 2 [10].

Table 2. Properties of hydroxylammonium chloride and its solutions

	Temperature, °C			
	20	40	60	80
Solubility, wt %				
Water	46.6	54.5	62.6	70.8
Methanol	14	17	21	
Density (saturated solution), g/cm^3				
Water	1.215	1.245	1.278	1.314
Methanol	0.867	0.870	0.878	

3. Chemical Properties

Hydroxylammonium salts decompose on heating; runaway exothermic decomposition can take place as a result of local heating. Decomposition is promoted by heavy-metal impurities, particularly, copper, copper-containing alloys, and copper salts. The decomposition products of the sulfate are sulfur dioxide, dinitrogen monoxide (nitrous oxide), water, and ammonium sulfate; the chloride decomposes to hydrogen chloride, nitrogen, water, and ammonium chloride.

Hydroxylammonium salts react with alkali to give the easily decomposed hydroxylamine. With nitrites, decomposition to dinitrogen monoxide occurs.

Aqueous solutions of hydroxylammonium salts are acidic. Long periods at 80 °C lead to slow decomposition. Solutions of hydroxylamine and its salts are radical traps, whereby ammonia and nitrogen are formed.

Oxidation leads, depending on the oxidant and reaction conditions, to nitrogen compounds in various oxidation states. Strong reducing agents such as zinc or iron powder give ammonia. Many metal ions form complexes with hydroxylamine.

With oleum or chlorosulfonic acid, hydroxylammonium salts yield hydroxylamine-*O*-sulfonic acid. The latter is a suitable reagent for amination, reductive deamination, hydroxymethylation, and formation of heterocycles [11].

Hydroxylamine can react at both the nitrogen and the oxygen atoms; for preparation of O-substituted hydroxylamines the nitrogen atom must be protected to avoid N-alkylation [12].

Hydroxylammonium compounds react with aldehydes and ketones to form oximes:

β-Diketones and β-dialdehydes form hydroxylamine isoxazoles.

With carboxylic acids and their derivatives, the products are the corresponding hydroxamic acids:

Reaction with isocyanates and nitriles gives *N*-hydroxyureas and amidoximes, respectively:

Hydroxylamine also reacts with olefinic double bonds:

4. Production

Industrial production of hydroxylamine is carried out by reduction of the higher oxidation states of nitrogen. For example, nitric oxide or nitric acid can be hydrogenated catalytically to hydroxylamine. For the reduction of nitrous acid to hydroxylamine, sulfurous acid is used. In all cases the product is an aqueous solution of a salt $NH_2OH \cdot HX$ (where HX is an acid, e.g., sulfuric or phosphoric acid) or $(NH_3OH)X$, rather than free hydroxylamine. Acid hydrolysis of primary nitroalkanes, with simultaneous formation of the corresponding carboxylic acid, plays only a minor role in the production of hydroxylamine (see Section 4.4).

4.1. Catalytic Hydrogenation of Nitric Oxide

To produce nitric oxide of high purity, ammonia and oxygen are reacted together over a platinum–rhodium catalyst at a temperature above 900 °C, the reaction gas being diluted with enough water or water vapor to bring the mixture below the lower explosion limit.

The byproduct, nitrogen dioxide, and excess oxygen are subsequently hydrogenated over a silver catalyst to nitric oxide and water, respectively.

After condensation and simultaneous recovery of water vapor, nitric oxide is purified in a washer and converted to hydroxylamine by reaction with hydrogen below 50 °C over a suspension of partially poisoned platinum catalyst in sulfuric acid. Small amounts of ammonium sulfate and dinitrogen monoxide are produced as byproducts.

$$2\,NO + 3\,H_2 + H_2SO_4 \xrightarrow{\text{Cat.}} (NH_3OH)_2SO_4$$

A continuous multistep process, in which the exhaust gases are extensively recirculated, has proved itself industrially [13], [14]. Residual gas, composed of hydrogen, nitrogen, nitric oxide, and dinitrogen monoxide, can be burned for recovery of steam. Explosive gas mixtures can be avoided in the synthesis of hydroxylamine by the choice of suitable gas composition.

A modified process for the catalytic hydrogenation of nitrogen monoxide, in which both cyclohexanone oxime and hydroxylamine are produced (acidic oximation), is discussed in → Caprolactam.

4.2. Catalytic Hydrogenation of Nitrates

Hydroxylamine is produced in the hydroxylamine – phosphate – oxime (HPO) process by hydrogenation of ammonium nitrate solution in phosphoric acid in combination with synthesis of cyclohexanone oxime for production of caprolactam [15]. This process is described in → Caprolactam.

4.3. The Raschig Process

The Raschig process [9], sometimes modified [16], remains an important process for the production of hydroxylamine.

Water, ammonia, and carbon dioxide react together in an absorption column to give a solution of ammonium carbonate, which forms an alkaline solution of ammonium nitrite with nitrogen oxides at low temperature:

$$(NH_4)_2CO_3 + NO + NO_2 \longrightarrow 2\,NH_4NO_2 + CO_2$$

In a further step, the ammonium nitrite is converted to ammonium hydroxylamine disulfonate with sulfur dioxide:

$$2\,SO_2 + NH_4NO_2 + NH_3 + H_2O \longrightarrow HO{-}N(SO_3NH_4)_2$$

In this process, excess ammonium hydroxylamine disulfonate is recycled. The ammonium hydroxylamine disulfonate solution is drawn off and the salt is hydrolyzed and neutralized to give hydroxylammonium sulfate and ammonium sulfate as products.

$$HO{-}N(SO_3NH_4)_2 \xrightarrow{H_2O} HO{-}NHSO_3NH_4 + (NH_4)HSO_4$$

$$(NH_4)HSO_4 \xrightarrow{NH_3} (NH_4)_2SO_4$$

$$2\,HO{-}NHSO_3NH_4 \xrightarrow{H_2O} (NH_3OH)_2SO_4 + (NH_4)_2SO_4$$

4.4. Acid Cleavage of Nitroalkanes

Mixtures of nitropropane and nitromethane can be cleaved to hydroxylammonium sulfate and

the corresponding carboxylic acid by sulfuric acid at elevated temperature [17]:

$$2\ RCH_2NO_2 \xrightarrow[H_2SO_4]{H_2O} (NH_3OH)_2SO_4 + 2\ RCOOH$$

This process has been used only to a limited extent because of its cost and the limited availability of raw materials.

4.5. Production of Crystalline Salts

Catalytic hydrogenation of nitric oxide leads to solutions of hydroxylammonium salts, which, after removal of the hydrogenation catalyst and neutralization with ammonia if required, can be allowed to crystallize [18]. The Raschig process leads initially to an oxime; acid hydrolysis, removal of the ketone, and subsequent crystallization give the solid salt.

With the intregrated hydroxylamine – cyclohexanone oxime process for production of caprolactam, the solid salts are also, in principle, accessible by acid hydrolysis of the oxime.

5. Safety and Environmental Protection

Safety. Hydroxylammonium sulfate and chloride are not combustible. Above 120 °C, however, they decompose exothermically with evolution of gas. Neither salt is sensitive to shock or friction.

For hydroxylammonium sulfate, differential thermal analysis (DTA) shows that an exothermic reaction begins at 138 °C and reaches a maximum at 177 °C. For hydroxylammonium chloride, the decomposition reaches its maximum at 144 °C.

The heat accumulation test with hydroxylammonium chloride shows an exothermic reaction which begins at 120 °C and reaches a maximum temperature of 280 °C.

Decomposition of hydroxylammonium salts can be countered with water. Although dry hydroxylammonium salts are not caustic or corrosive, aqueous solutions are acidic, and even the damp salts cause considerable corrosion of many metals.

Environmental Protection. Concentrations of hydroxylammonium compounds above 5 mg/L can cause inhibition of activated sludge, thereby impairing sewage-plant performance. The toxicity of hydroxylammonium compounds can be neutralized by oxidation to nitrates with microorganisms. Hydroxylamine is a natural intermediate in the metabolism of nitrification and denitrification bacteria.

In aqueous solution, hydroxylamine can be decomposed with nitrite salts or hydrogen peroxide.

6. Quality Specifications

Hydroxylamine producers are, generally, also hydroxylamine consumers. Quality requirements and quality control are therefore determined by the standards of the specific company.

The product is free of nitro and nitroso compounds, and contains no amines other than hydroxylamine. The pH is ca. 1.2 (20 °C).

Table 3. Typical specificationsfor hydroxylammonium salts

	Hydroxylammonium salt	
	Sulfate	Chloride
Hydroxylammonium salt (min), wt %	99.0	99.0
Free acid (HCl) (max.), wt %	[a]	0.2
Ammonium salts (max.), wt %	1.0 [b]	0.3 [c]
Chloride (max.), mg/kg	1	[a]
Sulfate (max.), wt %	[a]	0.1
Combustion residue (max.), mg/kg	10	20
Heavy metals, [d] mg/kg	1	1
Iron (max.), mg/kg	3	3

[a] Not applicable.
[b] Sulfate.
[c] Chloride.
[d] Calculated as Pb, excluding Fe.

In the limited market for hydroxylammonium salt solutions, quality specifications are based on chemical aspects (e.g., hydroxylamine content), foreign matter such as ammonium salts, or other impurities. A typical quality specification (BASF) for hydroxylammonium sulfate solution is:

Hydroxylamine, NH_2OH (min.)	113 g/L
Hydroxylammonium sulfate, $(NH_3OH)_2SO_4$, (min.)	280 g/L
Free sulfuric acid (max.)	20 g/L
Ammonium sulfate (max.)	25 g/L
Iron (max.)	10 mg/L
Density, d^{20}, (min.)	1.170 g/cm^3
Solidification point	−7 °C

Typical specifications (BASF) for crystalline hydroxylammonium sulfate and chloride are given in Table 3. Specifications and analytical methods vary with producer.

7. Analysis

Hydroxylamine and ammonia can be determined titrimetrically. Reaction of hydroxylamine salts with cyclohexanone leads quantitatively to cyclohexanone oxime and a mineral acid. The amount of mineral acid formed is a measure of the hydroxylamine content of the solution; it can be determined by potentiometric titration at pH 5.5. Reaction of ammonium salts with formaldehyde gives quantitative formation of hexamethylenetetramine and mineral acid. The quantity of mineral acid is a measure of the ammonium content and can be determined by potentiometric titration at pH 8.5.

Determination of possible traces of heavy metals can be carried out by the usual methods.

8. Storage and Transportation

The transportation of hydroxylammonium salts is subject to the following regulations:

1)
Hydroxylammonium sulfate:

GGVE/GGVS:	Class 8, no. 27 c
RID/ADR:	Class 8, no. 27 c
GGVSee/IMDG Code:	Class 8
IATA-DGR:	2865-III
UN no.:	2865

2)
Hydroxylammonium chloride:

GGVE/GGVS:	Class 8, no. 27 c
RID/ADR:	Class 8, no. 27 c
GGVSee/IMDG Code:	Class 8
IATA-DGR:	1759-III
UN no.:	1759

Hydroxylammonium sulfate and chloride are classified as X_n, harmful to health.

Hydroxylammonium sulfate solutions can be stored at up to 40 °C in stainless steel or polyethylene containers. Crystalline hydroxylammonium sulfate and chloride may be stored in a well-aired place below 45 °C; protection from moisture is recommended. With longer storage periods, caking may occur, although the quality of the material is not affected. To avoid vigorous reactions, the contact of hydroxylammonium salts with powders of heavy metals (e.g., copper, zinc, or iron), heavy metal salts (including nitrates and nitrites), oxidants, and alkali must be prevented.

Storage in the vicinity of heat sources such as steam pipes, heating, naked flames, or welding operations, the direct action of ignition sources, and heating of closed containers must be avoided because of the danger of violent decomposition.

Hydroxylamine is used mainly as the sulfate salt, supplied as both an aqueous solution and crystalline material. Aqueous solutions of hydroxylammonium sulfate are shipped in vehicles with tanks or tank containers of stainless steel or polyethylene. Crystalline hydroxylammonium sulfate is supplied packed in polyethylene sacks.

9. Uses

More than 95 % of hydroxylamine production is used to produce cyclohexanone oxime or caprolactam. Depending on patents and available technology, various producers use either hydrogenation or the Raschig process. The differences lie mainly in the amount of ammonium sulfate produced in oximation (→ Caprolactam, Chap. 4.1.).

Hydroxylammonium salts are also used in many branches of the chemical industry as a stable form of hydroxylamine because of the ease with which they undergo reactions. Some applications include the following:

1) *Chemical industry:* a reactant for the production of oximes as intermediates; an oxidizing or reducing agent, depending on pH
2) *Paints and coatings:* production of special oximes for use in anticreaming agents
3) *Pharmaceuticals:* production of antibiotics, steroids, tranquilizers, spasmolytics, and antitubercular drugs
4) *Photography:* stabilizer for developers; additive for color emulsions
5) *Rubber industry:* regulator in the polymerization of synthetic rubber; antioxidant for natural rubber; accelerator for the vulcanization of synthetic rubber
6) *Soap:* auxiliary for refining fats for soap production
7) *Plastics:* regulator and inhibitor in various polymerizations
8) *Metallurgy:* additive for surface treatment of steel; auxiliary for metal extraction from electrolysis waste liquor and for reclaiming spoil tips; flotation agent for copper ores
9) *Nuclear industry:* auxiliary for separation of uranium and plutonium
10) *Textiles:* auxiliary for specific dyeing processes; fixative for textile dyes; starting material for textile dyes based on isatin and isoxazole
11) *Crop protection:* starting material for production of insecticides, herbicides, and plant growth regulators
12) *Food:* intermediate in the production of sweeteners

10. Toxicology and Occupational Health

Hydroxylammonium compounds are irritant and considered harmful to health [19]. The LD_{50} (oral, rat) is ca. 600 – 640 mg/kg. The toxicity to fish, determined as LC_{50} (golden orfe, 48 h), is 1 – 10 mg/L for hydroxylammonium sulfate [5], [10], [19].

The primary effect of hydroxylamine on the skin (rabbit, BASF method) is slight to moderate irritation. Sensitization is possible after skin contact. The primary effect on mucous membranes (rabbit eye, BASF method) is moderate to strong irritation. Hydroxylamine is absorbed through the skin and acts to form methemoglobin.

Examination of the teratogenic effect (in rats) shows no harmful effects on progeny. According to results obtained to date, hydroxylamine and its salts are not carcinogenic, although they are mutagenic toward lower organisms.

Contact with hydroxylammonium salts should be avoided because of the irritant effect and the effect of the dust on skin, eyes, and throat. In the event of contact with the skin or eyes, the affected parts should be rinsed copiously with water. Hydroxylammonium salts must not be swallowed; if necessary, a physician should be consulted. Hydroxylammonium salts are to be labeled as dangerous materials.

1. Introduction

Hypnotics (Greek $\upsilon\pi\nu o\zeta$, sleep) are drugs that promote the onset of sleep and induce a state similar to natural sleep by depressing the central nervous system [1–28]. Hypnotics are not a sharply defined group of drugs because their sleep-inducing effect greatly depends on the dose. Small doses of a hypnotic have a sedative action; increasing doses cause, in succession, a hypnotic effect, a narcotic effect, and finally severe respiratory depression and death.

Sleep that is properly induced by drugs appears to resemble physiological sleep closely. Both states share the following symptoms:

– reduction of heart rate
– reduction of metabolism
– decrease in concentration of calcium ions in blood
– decrease in muscle tone and blood pressure
– contraction of bronchi and
– contraction of pupils

In contrast to narcotized persons, sleeping persons can be awakened.

Physiology of Sleep. Marked differences between drug-induced sleep and physiological sleep can, however, be detected by using polygraphic methods, such as measurement of pH changes and eye movements (electrooculogram), electromyogram, and electroencephalogram (EEG). On the basis of data obtained from these methods, two types of sleep of importance for the restoration of the body have been described:

1) *Orthodox, synchronized sleep* or nonrapid eye movement (NREM, nonREM) sleep can be distinguished by δ waves corresponding to periods of reduced activity on the EEG (δ sleep). Since these waves are slow, this phase is also referred to as slow wave sleep (SWS).
2) *Paradox sleep* or rapid eye movement (REM) sleep has high EEG activity.

The two types of sleep form a cycle of 110–140 min; four to five cycles are observed in adults each night (Fig. 1). Sleep is extremely important for the renewal of strength. The main phases of natural sleep are an initial deep, dreamless sleep, during which the body temperature falls, and a light, dream-filled, restless sleep before waking. The depth of orthodox sleep has four levels, as seen on the EEG (Fig. 1A), which can partly be correlated with certain body functions [10].

The areas of the brain that regulate body temperature and the sleep–wake cycle are close to each other and are functionally related. The modulations of sleep are correlated with the circadian rhythm of body temperature. The onset of sleep at night coincides with a lowering of body temperature, characteristic of NREM sleep. People who display a temperature difference of less than 1 °C are short sleepers and those

Figure 1. Different phases of normal adult sleep (ca. 8 h)
A) Electroencephalogram; B) Depth of sleep; C) Body temperature; D) Body movement

who display larger differences (>1 °C) are long sleepers. Body tissues are regenerated during orthodox sleep, and cerebral functions during the REM phase.

The REM phases account for ca. 20 – 25 % of sleep and appear to be periods of relatively high cerebral activity in which dreams occur. They are detected by measuring the spontaneous movements of the closed eye. In the absence of these dream phases sleep is not restful. Dreams are of great importance for learning and memory; they assimilate the experiences of the preceding days. Generally, dreams can be remembered slightly or not at all. With increasing age, the duration of REM sleep steadily decreases to about 20 – 30 % of its original duration. The REM phase is especially activated when a person is confronted with an emotionally arousing, intellectual task calling for creative effort, i.e., when alterations in thinking or behavior are necessary. Confrontation with problems also intensifies REM sleep, e.g., an astronaut experiences greatly increased REM sleep in his first night in space. Continuous suppression of REM sleep leads to psychological disturbances and psychosomatic symptoms.

1.1. Amino Acids and Hormones Influencing Sleep

Three *neurohormones* are involved in controlling sleep: serotonin, noradrenaline, and acetylcholine. Serotonin regulates orthodox sleep, whereas acetylcholine and noradrenaline influence the REM phase. The rates of cell division are the highest during sleep, and large amounts of *growth hormone* (GH), which stimulates pro-

tein synthesis, are secreted during the third and fourth levels of orthodox sleep. The EEG waves at this stage are also large and slow.

Melatonin is rhythmically secreted by the pineal gland. It stimulates specific receptors in the body's biological clock, the suprachiasmatic nuclei of the hypothalamus and may thus regulate the human circadian rhythm by increasing serotonin levels. The human biological clock can be "adjusted" with exogenous melatonin. Continous exposure of humans to light leads to sleep disorders by inhibiting melatonin synthesis [16], [29], [30].

A sleep inducing nonapeptide, *delta-sleep-inducing peptide* [*62568-57-4*] (DSIP), has been isolated from rabbit serum. This peptide, which also occurs in humans, has been synthesized and has been prepared by genetic engineering techniques. DSIP coordinates the rhythmic circadian sleep – wake cycles by promoting sleep functions (without having a sedative effect), and enhances mental performance when awake. At the same time, DSIP invokes a higher tolerance to stress. The action of this nonapeptide is attributed to modulation of the adrenergic receptors [31].

L-*Tryptophan,* a common amino acid found in the human body is a precursor of serotonin. In daily doses of 4 – 7 g it causes sedation during the day and a shortening of latency of sleep at night. It is registered in Switzerland as a "biological sleep-inducing drug." However, studies have questioned the sleep-modulating effect of this amino acid [32].

1.2. Influence of Hypnotics on Sleep

Most hypnotic drugs shorten both phases of sleep and suppress the paradoxical (REM) phase. Thus, the sleep curve is levelled out, and the EEG resembles that of a narcotized person. Hence, drug-induced sleep does not have the restorative quality of natural sleep and is no substitute for the treatment of insomnia. A research report of the Max Planck Institut für Psychiatrie (München, 1980) states that conventional sleep-inducing drugs do not produce restful sleep; since drug-induced sleep is not identical to natural sleep, taking sleeping pills is not advised. Pharmacologists also recommend the use of hypnotic drugs only for a few days, if at all, because of their many adverse effects. Alcohol should not be taken with sedatives or hypnotics because the reactions of the patient are then adversely affected.

Prolonged use of sedatives and hypnotics reduces their effect on the cells of the central nervous system (see also Section 5.1). Most hypnotics, particularly highly active preparations, can create psychological and physical dependence, resulting in withdrawal symptoms when treatment is terminated. In addition, many hypnotic drugs that suppress and shorten the REM phase produce a *rebound effect*, i.e., a sudden withdrawal after extended periods of use causing a prolongation of the REM phase. As in alcohol withdrawal, this effect can even lead to delirium tremens. In this way, the body tries to make up for lost REM sleep.

1.3. Requirements of Hypnotics

There is still no completely satisfactory hypnotic drug. The following requirements can be defined for an ideal hypnotic:

- reliable effect
- wide therapeutic range
- limited duration of action, no longer than 8 h
- physiological sleep
- no disturbance of deep sleep or REM sleep
- low toxicity
- no enzyme induction
- no respiratory depression
- no additive effect with alcohol
- no amnesia, confusion, or ataxia after arousal in the night
- no excessive daytime sedation
- no loss of potency on repeated use
- no risk of dependency, e.g., insomnia after termination of treatment
- no after effects (e.g., hangover)

1.4. Applications of Hypnotics

Sleep-inducing drugs are used by the following groups:

1) healthy people with demanding jobs or irregular working hours, who often take sleeping pills after stimulants such as coffee;

2) sick people with symptoms such as fever, sore throat, or cold;
3) old people with insomnia due to cerebral sclerosis usually have an inverted day – night rhythm; they are awake and mobile at night, and tired and peaceful in the morning.
4) sick people with uncomfortable and sleepless nights due to pain, who have difficulty in breathing, heart trouble, etc.; and
5) bedridden people with serious illnesses, who are deprived of physical exercise.

People belonging to groups 1 and 2 can be treated with mild relaxants by reducing the susceptibility of the reticular formation (site of the center of wakefulness in the brain) to external stimuli. These substances include plant components with sedative properties, such as valerian and hop, and tranquilizers or sedatives which, even in high doses, do not have narcotic properties. People belonging to groups 4 and 5 may have to be treated for extended periods with hypnotics and even with antipsychotic and antidepressant drugs.

1.5. Consumption of Hypnotics

The importance of hypnotic drugs is reflected in the fact that 21 % of the population of France (February 1975) and 32 % of the inhabitants of Los Angeles (1973) suffered from insomnia. In France, 2.5×10^6 tablets, capsules, and dragées are taken every evening to promote sleep [33–38]. The dramatic increase in the consumption of hypnotics with age can only be partly justified because older people require less sleep at night. Instead, they have a more pronounced endogenous sleep profile with increased cerebral readiness to sleep at 9.00, 13.00, and 17.00 h.

1.6. Classification and Evaluation of Hypnotics

Hypnotics may be classified as follows [34]:

1) benzodiazepine hypnotics;
2) nonbenzodiazepine hypnotics, e.g., chloral hydrate, barbiturates, piperidinediones, and methaqualone;
3) other drugs with sedative effects, (e.g., tranquilizers, antidepressants, and antihistamines); and
4) natural preparations, e.g., valerian, ethanol, and DSIP.

There is no sharp distinction between sedatives and hypnotic drugs; differences in activity are quantitative rather than qualitative. Both inhibit the activation system in the reticular formation. Drugs belonging to groups 1 and 2 are true hypnotics. Drugs belonging to group 3 are only occasionally used as hypnotics.

Der Bewertende Arzneimittelindex (The Valuating Drug Index) assesses "benzodiazepine sleep-inducing drugs" positively, especially because of their wide therapeutic range [37]. Other recommended drugs are chloral and its derivatives (see Sections page 7page 7), diphenhydramine, and doxylamine (see Sectionpage 5). Derivatives of barbituric acid, piperidinediones, and quinazolinones are not recommended. In comparison with the benzodiazepines, these cause more undesirable effects (respiratory depression, negative influence on REM sleep, enzyme induction, and problems of dependence). Their therapeutic range is narrow. Compounds containing bromine are also to be avoided because they may cause bromism (see Chap. 2). Valerian preparations (e.g., Valepotriate) and their components are not favored because of their in vitro cytotoxic and alkylating action. The therapeutic importance of these drugs cannot be assessed at present [37].

The lists of trade names cited for individual hypnotics are not complete.

2. Sedatives, Antihistamines, and Tranquilizers

Sedatives and Tranquilizers. There is no significant distinction between sedatives and hypnotics; the same drugs are often used for both purposes. Sedatives (→ Sedatives) and tranquilizers (→ Psychopharmacological Agents) are used to sedate and relieve anxiety during the day and, in addition, to induce sleep at night. Therapeutic doses of tranquilizers have a calming, relaxing effect and alleviate psychological symptoms such as fear, anxiety, restlessness, and tension. Ideally, they should not produce sedative

or hypnotic effects. The first therapeutically used hypnotics were plant extracts with either sedative (valerian root and hop) or analgesic action (opium alkaloids). In spite of the sedative effect of opium alkaloids [39], they should not be used for obvious reasons (addiction, euphoria, poor dose adjustment, and legality). Of all the plant extracts available, only one substance, valmane, is exactly defined from a chemical standpoint.

Valepotriate is a mixture of valtratum [*18296-44-1*] (**1**), acevaltratum [*25161-41-5*] (**2**), and didrovaltratum [*18296-45-2*] (**3**):

1: $R^1 = R^2 = CH(CH_3)_2$, $R^3 = CH_3$
2: $R^1 = CH(CH_3)_2$, $R^2 = C(CH_3)_2-O-CONH_2$, $R^3 = CH_3$

3: $R^1 = H$, $R^2 = CH(CH_3)_2$, $R^3 = CH_2-CH(CH_3)_2$

These three compounds, which occur in nature in the root of *Valeriana officinalis*, have a sedative, mildly psychotropic action. They act as mild hypnotic agents because they restore physiological equilibrium in vegetative disorders. The activity of valmane has been questioned [38].
Trade Names. Valmane (Kali-Chemie, FRG), Nevripan (Medopharm, FRG).

Simple *bromine-containing sedatives* (sodium, potassium, or calcium bromide, or the hydrobromides of magnesium glutamate or magnesium aspartate) should not be used under any circumstances. If given for long periods, they cause a mental condition known as bromism, which is characterized by symptoms such as loss of concentration and memory, insomnia, rash, and psychoses.

Antihistamines. The following antihistamines have sedative properties and are sometimes used as hypnotics:

Meclozine or Meclizine [*569-65-3*], 1-[4-chlorobenzhydryl]-4-(3-tolyl)piperazine dihydrochloride (→Antiallergic Agents, Chap. 2.1.4.)
Trade Names: Calmonal (Heiden, FRG), Bonine (Pfizer, USA).

Diphenhydramine hydrochloride [*147-24-0*], 2-(benzhydryloxy)-*N,N*-dimethylethylamine (→Antiallergic Agents)
Trade Names: Benadryl (Parke-Davis, USA), Halbmond (Much, FRG).

Doxylamine succinate [*562-10-7*], 2-dimethylaminoethoxyphenylmethyl-2-picoline
Trade Names. Decapryn, Meteprine (Merrell, USA), Unisom (Pfizer, USA).

Psychopharmacological Agents. Of the large number of tricyclic antipsychotropic drugs available, two are used as hypnotics:

Perimetazine [*13093-88-4*], perimethazine, 1-[3-(2-methoxyphenothiazin-10-yl)-2-methylpropyl]-4-piperidinol, $C_{22}H_{28}N_2O_2S$, M_r 384.54 (→Phenothiazines and Derivatives).
Trade Name. Leptryl (Roger Bellon, USA).

Perlapine [*1977-11-3*], 6-(4-methyl-1-piperazinyl)-11*H*-dibenz[*b,e*] azepine, $C_{19}H_{21}N_2$, M_r 291.40, *mp* 136 – 138 °C.

This compound, in the form of yellow prisms, is prepared by chlorinating 11*H*-dibenz[*b,e*] azepin-6-one with phosphoryl chloride to give the imide chloride, which is subsequently treated with *N*-methylpiperazine [40]. The compound thus obtained has hypnotic properties [41]; LD_{50} (oral) 415 mg/kg (mouse).
Trade Names. Hypnodine (Wander, FRG; Takeda, Japan), Pipnodine (Takeda, Japan).

3. Alcohols and Aldehydes

The discovery that after producing an initial excitation phase, ethanol has a general sedative action, led to the development of tertiary and halogenated alcohols as hypnotics. These substances are rarely used today. Chloral hydrate has long-lasting sedative and hypnotic effects because it is metabolized in the body to 2,2,2-trichloroethanol, which also has a sedative action.

Methylpentynol [*77-75-8*], 3-methyl-1-pentyn-3-ol, $C_6H_{10}O$, M_r98.14, *bp* 121–122 °C, is a highly mobile liquid with a pungent smell and burning taste. It solidifies at −30.6 °C and is soluble in almost all organic solvents. It is produced by reacting 2-butanone with sodium acetylide.

As a result of its short duration of action (0.5–1 g act for 1–2 h), this preparation is especially useful in promoting sleep in cases of mild insomnia.
Trade Names. Atemorin (Scherer, USA), Dalgol, Dorison, Dormison (Schering Corp., USA), Pentadorm (Ruef, Austria), Somnesin (British Drug Houses, UK), Util (Leo, Denmark).

Ethchlorvynol [*113-18-8*], 3-(*β*-chlorovinyl)-3-hydroxy-pent-1-ine, C_7H_9OCl, M_r 144.61, *bp* 173–174 °C, is a liquid with a pungent, aromatic smell. It darkens slowly when exposed to air and light. The compound is immiscible with water but miscible with most organic solvents.

It is prepared by reacting 1-chloropent-1-en-3-one with acetylene [42]. This preparation is a useful short-term hypnotic, but abuse can lead to habituation and addiction.
Trade Names. Roeridorm (Roerig, FRG), Arvynol (Pfizer, USA), Placidyl, Serenesil (Abbott, USA).

Paraldehyde [*123-63-7*], paracetaldehyde, 2,4,6-trimethyl-1,3,5-trioxane, $C_6H_{12}O_3$, M_r 132.16, *bp* 124 °C, is a colorless liquid with an aromatic smell and unpleasant taste. One part of paraldehyde is soluble in eight parts of water at 25 °C. For other properties and synthesis, see →Acetaldehyde, Chap. 8.1. This substance has an unpleasant taste and imparts a bad odor to the breath; addiction is possible. Paraldehyde is only used in clinics and is no longer prescribed.
Trade Names. Paraldehyde Thilo (Thilo, FRG; Fellows, USA), Paral (O. Neal, Jones & Feldmann, USA), Dannetène (Bottu, France).

Chlorethate [*5634-37-7*], bis(2,2,2-trichloroethyl)carbonate, $C_5H_4Cl_6O_3$, M_r324.82 is prepared by the reaction of phosgene with 2,2,2-trichloroethanol in the presence of a base [43], [44]. The insolubility of this substance prevents gastric irritation, which is produced by the hypnotically active parent compound, 2,2,2-trichloroethanol [44].
Trade Name. Clorets (Smith, Kline & French, USA).

Chloral hydrate [*302-17-0*], 2,2,2-trichloro-1,1-ethanediol, $C_2H_3Cl_3O_2$, M_r165.42, *mp* 57 °C, *bp* 98 °C (decomp. into chloral and water), is a crystalline substance with a pungent odor and taste. It is readily soluble in water, ethanol, diethyl ether, and chloroform. For production see →Chloroacetaldehyde, Chap. 3.3.

Doses of 0.5–0.75 g rapidly produce deep sleep, which lasts 4–8 h, without morning hangover. Standard doses of 0.5 g do not produce REM sleep, but doses of more than 0.8 g generally have a negative influence. Adverse effects are irritation of the mucous membranes and hepato- and nephrotoxicity. Prolonged administration can cause habituation, and physical and psychological addiction.
Trade Names. Ansopal (Ferrosan, Denmark), Aquachloral (Webcon, USA), Chloradorm (Knoll Lab., Australia), Chloraldurat (Pohl-Boskamp, FRG), Cohidrate (Coastal, USA), Escre (SS Pharmaceutical, Japan), H. S. Need (Hanlon, USA), Lanchloral (Lancet, Australia), Nervifene (Interdelta, Switzerland), Novochlorhydrate (Novopharm, Canada), Oradrate (Coast, USA), Somnos (Merck, Sharp & Dohme, USA), Suppojuvent Sedante (Juventus, Spain).

Chloral Derivatives.
Chloral betaine [*2218-68-0*], $C_7H_{14}Cl_3NO_4$, M_r 282.57, *mp* 122.5–124.5 °C, is prepared from betaine hydrate and chloral hydrate [45]. This adduct has the same hypnotic properties and contraindications as chloral hydrate, but it does not have the unpleasant physical properties.

Trade Names. Beta-Chlor (Mead Johnson, USA) Somilan (British Drug Houses, UK), Somnalchlor (Schiaparelli, Italy).

Triclofos [*306-52-5*], 2,2,2-trichloroethyl dihydrogen phosphate, $C_2H_4Cl_3O_4P$, M_r229.39.

The sodium salt, *triclofos sodium* [*7246-20-0*], $C_2H_3Cl_3NaO_4P$, is soluble in water. This preparation has the same physiological properties as chloral hydrate, but it does not have the unpleasant physical characteristics. The compound is metabolized in the body mainly to the hypnotically active 2,2,2-trichloroethanol. A dose of 1.5 g is equivalent to 1 g of chloral hydrate.

Trade Names. Triclos (Lakeside, USA), Triclosyl (Glaxo, UK), Tricloran (C.T.S. Israel).

Petrichloral [*78-12-6*], pentaerythritchloral, $C_{13}H_{16}Cl_{12}O_8$, M_r725.76, *mp* 52 – 54 °C [46].

Chloralodol [*3563-58-4*], chlorhexadol, 2-methyl-(2′,2′,2′-trichloro-1′-hydroxy-4-ethoxy)-pentan-2-ol, $C_8H_{15}Cl_3O_3$, M_r 265.58, *mp* 102 – 124 °C [47].

Trade Names. Lora (Wallace, USA), Mechloral, Mecloral (Dumex, Denmark).

Chloralose [*15879-93-3*], α-*O*-(2,2,2-trichloroethylidene)-1,2-α-D-glucofuranose-(*R*), $C_8H_{11}Cl_3O_6$, M_r309.54, *mp* 187 °C, $[\alpha]_D^{22}$ + 19 (5 % solution in 98 % ethanol) [48].

Trade Names. Chloralosan (Kuhlmann, France), Somio (Sidel, France).

Carbocloral [*541-79-7*], *N*-(2,2,2-trichloro-1-hydroxyethyl)- ethyl carbamate, $C_5H_8Cl_3NO_3$, M_r 236.49, *mp* 103 °C (decomp.) [49].

Trade Name. Prodorm (Parke-Davis, USA).

4. Urethanes, Acyclic Urea Derivatives, and Amides

These compounds are mild hypnotic agents. They are generally used to promote the onset of sleep or as daytime sedatives, often in combination with weak analgesics. They are well-absorbed and, depending on the structure, have few side effects. Dependence on these compounds occurs less frequently than on barbiturates and benzodiazepines.

Urethane [*51-79-6*], ethyl carbamate, a mild hypnotic agent, is no longer prescribed because its cytostatic properties can cause agranulocytosis on prolonged administration.

Ethinamate is the most important carbamate. Some other derivatives of carbamic acid are used as central muscle relaxants (→Skeletal Muscle Relaxants) and as psychotropic drugs (→Psychopharmacological Agents).

Ureides are still widely prescribed as mild sedatives and hypnotic agents. They are used alone and in combinations. However, bromine-containing derivatives should be given with great care because of the danger of bromism.

Most *amides,* especially those of simple branched fatty acids, have only a mild sedative action, but some are frequently used to promote sleep.

Ethinamate [*126-52-3*], 1-ethynylcyclohexylcarbamate, $C_9H_{13}NO_2$, M_r167.21, *mp* 96 – 98 °C, solubility in water 0.25 %, in ethanol 35 %, and

in hexane 2 %, is produced by treating 1-ethynylcyclohexan-1-ol with (1) carbamic acid chloride in the presence of sodium amide [50] or (2) with phosgene and ammonia [51].

Trade Names. Valamin (Schering, FRG), Valmid, Valmidate (Lilly, USA).

Hexapropymate [*358-52-1*], 1-(2-propynyl)cyclohexanol carbamate, $C_{10}H_{15}NO_2$, M_r 181.23, *mp* 99 °C, is synthesized as described for ethinamate [52].

Trade Names. Merinax (Labaz, France), Mekos (Helsingborg, Sweden).

Carfimate [*3567-38-2*], 1-phenyl-2-propynyl carbamate [53], $C_{10}H_9NO_2$, M_r 175.18, *mp* 86 – 87 °C, is a hypnosedative.

Trade Names. Equilium (Delagrange, France), Nirvetil, Nirvotin (Erba, Italy).

Ectylurea [*95-04-5*], *cis*-(2-ethylcrotonoyl) urea, $C_7H_{12}N_2O_2$, M_r 156.18, *mp* 191 – 193 °C (also *mp* 158 °C), is prepared by treating (2-bromo-2-ethylbutyryl)urea with sodium hydroxide or by reacting carbromal with silver oxide [54]. It is a sedative with a mild hypnotic action.

Trade Names. Cronil (Farmigea, Italy), Distesol (Locatelli, Italy), Ectyl (ACO, Sweden), Levanil (Upjohn, USA), Neuroprocin (Minerva-Chemie, Netherlands).

Carbromal [*77-65-6*], 2-bromo-2,2-diethylacetylurea, $C_7H_{13}BrN_2O_2$, M_r237.11, *mp* 116 – 119 °C; 1 g of this compound dissolves in 3000 mL of water, 18 mL of ethanol, 3 mL of chloroform, and 14 mL of ether. It is soluble in alkaline solution and in concentrated sulfuric, hydrochloric, and nitric acids. The reaction of α-bromo-α-ethylbutyric acid bromide with urea at 50 °C produces carbromal [55]. The effects are attributed to the unchanged molecule, even though all the bromine in the organism is broken down to bromide. The same applies to acecarbromal and bromisoval.

Trade Names. Adalin (Bayer, FRG), Bromadyl (Vicario, France), Diacid (Rieswerke, Austria), Fydalex (Boots, UK), Hyperysin (Hommel, Switzerland).

Acecarbromal [*77-66-7*], acetylcarbromal, *N*-acetyl-*N′*-(2-bromo-2-diethylacetyl)urea, $C_9H_{15}BrN_2O_3$, M_r279.14, *mp* 109 °C, is slightly soluble in ethanol and ethyl acetate. It is prepared by the acetylation of carbromal with acetic anhydride in the presence of zinc chloride [56]. Abuse can cause habituation and addiction.
Trade Names. Abasin (Bayer, FRG; Winthrop, USA), Adityl, Carbased (Mallard, USA).

Bromoisoval [*496-67-3*], α-bromoisovalerylurea, $C_6H_{11}BrN_2O_2$, M_r 223.08, *mp* 147 – 149 °C, is soluble in hot water, diethyl ether, ethanol, and alkali. The compound is prepared by the acylation of urea with α-bromoisovalerylbromide [57].
Trade Name. Bromuvan (Treibacher Chem. Werke, Austria), Bromovaleryl, Bromyl (ACO, Sweden), Dagrabromyl (Dagra, Netherlands), Dormigene (Pharmacobel, Belgium), Isobromyl (Clin-Comar-Byla, France), Isoval (Mission, USA), Melosan (Allied Lab., USA).

Apronalide [*528-92-7*], 2-allyl-2-isopropylacetylurea, 1-(2-isopropyl-4-pentenoyl)-urea, $C_9H_{19}N_2O_2$, M_r184.23, *mp* 194 °C [58]. This compound is no longer produced in the Federal Republic of Germany because of its severe adverse effects (purpura hemorrhagica).
Trade Names. Dormid (Rohto, Finland), Neurokin (Leerbeck & Holm, Denmark), Sedormid (Roche, Switzerland).

Pheneturide [*90-49-3*], ethylphenacemide, 2-phenylbutyrylurea, $C_{11}H_{14}N_2O_2$, M_r206.24, *mp* 149 – 150 °C, is prepared by acylating urea with the α-phenylbutyric chloride [59]. It is not only used as a hypnotic agent, but also in the treatment of epilepsy.

Trade Names. Benuride (Bengue, UK; Vinas, Spain), Deturid (Polfa, Poland; Sapos, Switzerland).

Capuride [*5579-13-5*], 2-ethyl-3-methylvalerylurea, $C_9H_{18}N_2O_2$, M_r186.25, *mp* 172 °C [60].
Trade Name. Pacinox (McNeil, USA).

Valdettamil, Novonal [*512-48-1*], 2,2-diethyl-4-pentenamide, $C_9H_{17}NO$, M_r155.23, *mp* 75 – 76 °C, is soluble in 120 parts of water and freely soluble in alcohol and ether [61].
Trade Names. Insomnia (ICN, USA), and as combinations: Arantil (Hoechst, FRG), Dentigoa (Scheurich, Switzerland).

Butoctamidesemisuccinate [*32838-28-1*], *N*-(2-ethylhexyl)-3-hydroxybutyramide hydrogen succinate, $C_{16}H_{29}NO_5$, M_r 315.41, *mp* 36.5 °C, is prepared by the aminolysis of ethyl 3-hydroxybutyrate with 2-ethylhexylamine and the subsequent formation of the semiester of succinic acid [62].

Butoctamide is related to (1-methyl)heptyl γ-bromoacetate, which is found in human cerebrospinal liquid. It increases the brain 5-hydroxytryptamine level and has an antitumor effect. It is given in doses of 200 mg (approximately as effective as 400 mg of bromoacetylurea [63].

5. Cyclic Carboxamides, Carboximides, Cyclic Urea Derivatives, and Related Compounds

Most of the synthetic sleep-inducing drugs used today have a carboxylic acid amide group (**4** in Fig. 2) incorporated into a ring structure. The ring nitrogen atom is linked to many different structural elements (Fig. 2).

The following groups of compounds belong to this category:

N-acyl derivatives: cyclic imides, e.g., (**5**) and 2,6-piperidinediones (**10**)
diacylated cyclic ureas: barbiturates (**8**) and thiobarbiturates (**9**)
N-(β-carbonyl)ethyl derivatives: 2,4-piperidinediones (**6**)
N-iminoacyl derivatives: quinazolinones (**7**)
phenyl N-iminoacyl derivatives: benzodiazepines (**11**)

All groups, except **5**, **7**, and **11**, have a doubly substituted carbon atom adjacent to the carbonyl group of the amide structure. These substituents greatly influence the action and the distribution of the drug in the body.

Figure 2. Cyclic carboxamide, carboximide, and urea structures used in hypnotics.

5.1. Barbituric Acids [64–66]

The first representative of this group of substances, barbituric acid, was discovered in 1845 [67]. A synthesis of the first barbiturate with hypnotic properties, 5,5-diethylbarbituric acid (barbital), was completed in 1882; its effects were described in 1903. Since then about 60 different barbiturates have been introduced, of which 20 – 25 are still used in the industrial

Table 1. Duration of action dose, biological half-life, and metabolism of barbiturates

Compound	Type *	Mean hypnotic dose, g	Duration of hypnotic effect, h	Onset of action, min	Plasma protein binding, % **	Biological half-life, h	Proportion metabolized, %	pK value
Barbital	L	0.25 – 0.5	10 – 24	30 – 60	2	72 – 120	< 5	7.88
Phenobarbital	L	0.1 – 0.2	4 – 12	30 – 60		48 – 96	80	7.29
Butobarbital	L	0.05 – 0.1	6 – 12	30 – 60			95	8.12
Probarbital	L – M	0.12 – 0.25	4 – 12	30 – 60				
Amobarbital	M – L	0.1 – 0.3	2 – 8	15 – 30		15	>95	
Cyclobarbital	M	0.1 – 0.2	2 – 8	15 – 30			>99 (in 3 d 42 %)	7.80
Aprobarbital	M	0.065 – 0.13	2 – 8	15 – 30			80	8.15
Allobarbital	M	0.1 – 0.3	2 – 8	15 – 30			70	7.92
Vinylbital	M	0.15	6 – 7	15 – 30			35 in 4 d	
Heptabarb	S – M	0.1 – 0.4	2 – 4	30			98	7.78
Secbutabarbital	S – M	0.1	2 – 4	30				
Pentobarbital	S – M	0.1 – 0.2	2 – 4	30	40	15	99 (in 1 d 25 %)	7.88
Butallyonal	S – M	0.2	2 – 4	30			>90	8.00
Talbutal	S	0.12 – 0.15	2 – 4	30				
Cyclopentobarbital	S	0.12 – 0.25	2 – 4	30				8.10
Propallyonal	S	0.1 – 0.3	2 – 4	30			>99	8.05
Secobarbital	VS – S	0.1 – 0.2	1 – 3	15	45		90	7.80
Hexobarbital	VS – S	0.25 – 0.4	1 – 4	15	2	3.5	95	8.30

* Duration of action: L = long; M = medium; S = short; VS = very short.
** Percentage of the barbiturate that is bound to the protein.

countries. Important properties are listed in Table 1. As hypnotics, barbituric acids all produce almost identical pharmacodynamic effects. However, they show wide differences in pharmacokinetics and metabolism. Differences in onset and duration of activity are related to lipid and water solubility, and rate of metabolism. Lipophilic barbiturates, e.g., the narcotically active, lipid-soluble thiobarbiturates, and the *N*-monoalkylbarbiturates such as hexobarbital rapidly disappear in adipose tissue. As a result of their redistribution in lipophilic compartments of the body, these compounds have a very short duration of action and are rapidly broken down (*short-acting narcotics*, →Anesthetics, General, Chap. 3.1.).

From a therapeutic standpoint, barbiturates used as hypnotic agents are classified according to their duration of action (see also Table 1):

1) *long-acting compounds* (barbital, phenobarbital),
2) *medium-acting compounds* (amobarbital, cyclobarbital),
3) *short-acting compounds* (hexobarbital), and
4) *compounds whose effects begin after 15 – 20 min* (secobarbital).

The duration of action is primarily determined by the rate of enzymatic degradation in the liver, which depends on the chemical structure of the barbiturate. Continual use causes *enzyme induction* in the liver and thus a gradual increase in the rate of barbiturate degradation. Increasing doses are required with prolonged use (*barbiturate habituation*). In some patients barbiturates not only have a sedative and hypnotic action, but also produce excitement and euphoria. This sense of well-being may easily lead to *barbiturate addiction*, a physical dependence with withdrawal symptoms. Barbiturate addicts take the hypnotic because of its euphoric properties and try to compensate for the central depression by using psychoanaleptic drugs.

Cases of accidental and suicidal barbiturate poisoning are fairly common. They are characterized by unconsciousness (which can precede a delirious stage), central respiratory depression accompanied by oxygen deficiency symptoms, and in severe poisoning circulatory collapse with death in 12 h to 4 d. The prognosis for barbiturate poisoning is favorable if treatment is immediate. Essential measures include artificial respiration, irrigation of the stomach, circulatory

support, forced osmotic diuresis using mannitol, exchange transfusion, and hemodialysis.

Barbiturates produce a condition superficially resembling natural sleep. However, the REM phase, which is very important for rest and recuperation, is shortened. Continued use of barbiturates leads to a very low REM value, and sudden withdrawal increases the REM phase (*rebound effect*). The adverse effects of barbiturates are well-documented after more than 50 years of experience. This is an important advantage over newly developed hypnotics [68].

The pK values of the hypnotically active barbituric acids, range between 7.78 and 8.30. Disubstituted barbituric acids are present, to ca. 50 %, in the undissociated form under physiological conditions (pH 7.4). Only this form of the drug can pass through biological membranes. The degree of dissociation is strongly influenced by slight alterations in pH.

Production. The 5,5-disubstituted barbituric acids are still synthesized by the classical condensation of substituted malonic esters (**12**), malonic amides, or cyanoacetic esters (**13**) with urea (**14**), thiourea (**15**), guanidine (**16**), or dicyanodiamide (**17**), followed by the hydrolysis of the resulting imino- or cyanobarbiturate [69] (Fig. 3).

Under acidic or neutral conditions, substituted malonic acids or malonic chlorides can also be used for the condensation with urea or thiourea. It is preferable for the substituents R^1 and R^2 to be present in the malonic ester or cyanoacetic ester molecule; disubstitution of barbituric acids at the 5-position is only possible with highly reactive halides, such as allyl halides.

Barbital [*57-44-3*], barbitone, 5,5-diethylbarbituric acid, $C_8H_{12}N_2O_3$, M_r 184.19, *mp* 188 °C, (sodium salt [*144-02-5*], $C_8H_{11}N_2NaO_3$, M_r 206.18), has a bitter taste. One part of the acid dissolves in 170 parts of water at 25 °C or 17 parts of water at 100 °C. It is freely soluble in acetone, ammonia, and lye. Barbital is prepared by the condensation of diethyl malonate with urea in the presence of sodium ethoxide [70]. Both the acid and its sodium salt are used as long-acting hypnotics; abuse can cause habituation or addiction.

Trade Names. Dormileno (Faes, Spain), Hypnox (Püschel, Austria), Veronal (Bayer, FRG; Merck, FRG), Veroletten (EAS-Labor, Austria).

Sodium salt: Barbinetten (Hormosani, Austria).

Phenobarbital [*50-06-6*], phenemalum, phenobarbitone, 5-ethyl-5-phenylbarbituric acid, $C_{12}H_{12}N_2O_3$, M_r 232.23, *mp* 174 – 178 °C. The acid crystallizes from water in the form of flakes. It is odorless, with a slightly bitter taste; an aqueous solution reddens litmus paper. One part dissolves in 1100 parts of water at 20 °C, 40 parts of boiling water, 10 parts of ethanol, 18 parts of diethyl ether, and 60 parts of chloroform. It is synthesized by the reaction of urea with ethyl phenyl malonate in sodium ethoxide solution [71].

The sodium salt of phenobarbital [*57-30-7*], $C_{12}H_{11}N_2NaO_3$, M_r 254.23, is a colorless, crystalline, hygroscopic, freely water-soluble powder. It is slightly soluble in ethanol, and insoluble in diethyl ether and chloroform. The aqueous solution is stable for only a short time.

Phenobarbital is a long-acting hypnotic with anticonvulsant properties. Long-term use in higher than therapeutic doses can cause physical addiction. An overdose resulting in blood levels of 8 – 12 mg/100 mL can cause death.

Trade Names. Agrypnal (Eggochemia, Austria), Aphenylbarbit (Streuli, Switzerland), Calminal (Wolfs, Belgium), Epsylone (Powell, Canada), Eskabarb Span (Smith, Kline & French, USA), Fenemal (DAK, Denmark), Gardenal (Specia, Canada), Gardenale (Farmitalia Carlo Erba, Italy), Hypnolone (Hartz, Canada), Pepinal, Lepinaletten (Arzneimittelwerk Dresden, GDR), Luminal (Bayer, FRG; E. Merck, FRG; Winthrop, USA), Mediphen (Medic, Canada), Phen Bar (Saunders, Canada), Phenobarbyl (Synochem, FRG), Seda-Tablinen (Beiersdorf, FRG), Solfoton (Poythress, USA), Teolaxin (Paul Maney, Canada); Phenobarbital diethylamine salt: Gratusminal (Farmasimes, Spain); Phenobarbital calcium salt: Fenileal (Turon, Spain), Lumcalcio (Abello, Spain).

Butobarbital [*77-28-1*], butobarbitone, 5-butyl-5-ethylbarbituric acid, $C_{10}H_{16}N_2O_3$, M_r 212.24, *mp* 124 – 127 °C, forms slightly bitter crystals; 1 g dissolves in 5 mL ethanol; preparation is described in [72]. It is a long-

Figure 3. Synthesis of barbiturates.

acting hypnotic; abuse can cause habituation or addiction.
Trade Names. Butenil, Butynoct (Interpharm, Austria), Etoval, Longanoct, Sonabarb (Protea, Australia), Soneryl (Specia, Italy; May & Baker, USA).

Probarbital [*76-76-6*], 5-ethyl-5-isopropylbarbituric acid, $C_9H_{14}N_2O_3$, M_r 198.22, *mp* 197 – 198 °C, is slightly soluble in cold water, but more soluble in hot water and ethanol. Sodium salt [*143-82-8*], $C_9H_{13}N_2NaO_3$, M_r 220.20, is a hygroscopic powder that is soluble in water. The calcium trihydrate [*545-74-4*], $C_{18}H_{26}CaN_4O_6 \cdot 3\,H_2O$, M_r 488.55, forms slightly bitter crystals; 1 g dissolves in 40 g water; preparation is described in [73]. Probarbital is a long- to medium-acting hypnotic; abuse can cause habituation or addiction.
Trade Names. Ipral Sodium, Ipral Calcium (Squibb, USA).

Amobarbital [*57-43-2*], 5-ethyl-5-isopentylbarbituric acid, $C_{11}H_{18}N_2O_3$, M_r 226.28, *mp* 156 – 158 °C, forms slightly bitter crystals; 1 g dissolves in 1300 mL water and in 5 mL ethanol. The sodium salt, $C_{11}H_{17}N_2NaO_3$ [*64-43-7*], M_r 248.25, is hygroscopic and readily soluble in water; preparation is described in [74], and metabolism in [75].

Amobarbitol is a widely used medium- to long-acting hypnotic. It resembles secobarbital and pentobarbital in action with a somewhat longer duration. A blood level of 3 – 6 mg/100 mL of blood is fatal; abuse can cause habituation or addiction.
Trade Names. Amsal (Adams, Australia), Amycal (AFI, Sweden), Amydorm, Amytal (Lilly, USA), Isobec (Pharbec, Canada), Isonal (ICN, Canada), Neur-Amyl (Fawns & McAllen, Australia), Placidel (Miquel, Spain). Stadadorm (Stada, FRG).

Amobarbital sodium: Altinal, Amsal (Adams, Australia), Amsebarb (Paul Maney, Canada), Amylbarb Sodium (Protea, Australia), Amylobeta (Bramble, Australia), Amytal Sodium (Lilly, USA), Barbamyl (Teva, Israel), Dorminal (Boots, UK), Neur-Amyl (Fawns & McAllen, Australia), Novamobarb (Novopharm, Canada).

Cyclobarbital [*52-31-3*], cyclobarbitone, 5-(1-cyclohexen-1-yl)-5-ethylbarbituric acid, $C_{12}H_{16}N_2O_3$, M_r 236,26, *mp* 171 – 174 °C, forms bitter crystals and is moderately soluble in water. The calcium salt [*143-76-0*], $C_{24}H_{30}CaN_4O_6$, M_r 510.59, is prepared by heat-

ing ethyl(1-cyclohexen-1-yl) cyanoacetate with guanidine sulfate in sodium ethoxide, followed by hydrolysis with dilute sulfuric acid [76]. One part dissolves in 70 parts of water. This compound is a medium-acting hypnotic; abuse can cause habituation or addiction.

Trade Names. Fabadorm (Bayer, FRG), Phanodorm (Bayer, FRG; Merck, FRG; Winthrop, USA), Phanotal (Kwizda, Austria).

Aprobarbital [*77-02-1*], 5-allyl-5-isopropylbarbituric acid, $C_{10}H_{14}N_2O_3$, M_r210.23, *mp* 140 – 141.5 °C, forms slightly bitter crystals, and is insoluble in water, but soluble in ethanol. The sodium salt [*125-88-2*], $C_{10}H_{13}N_2NaO_3$, M_r232.21, a hygroscopic, bitter powder, is soluble in water. Preparation is described in [77]. This compound is a medium-acting hypnotic; abuse can cause habituation or addiction.
Trade Names. Alurate (Hoffmann-La Roche, Switzerland), Numal (United Chemicals, USA).

Allobarbital [*52-43-7*], allobarbitone, 5,5-diallylbarbituric acid, $C_{10}H_{12}N_2O_3$, M_r 208.21, *mp* 171 – 173 °C, is slightly bitter. One part dissolves in 300 parts of cold water and in 50 parts of boiling water. It is prepared by heating diallyl malonate with urea in sodium ethoxide. It can also be synthesized by the reaction of barbituric acid with allyl bromide in the presence of sodium acetate or copper sulfate [78], [79]. It is a mediumacting hypnotic; abuse can lead to habituation or addiction.
Trade Names. Diadol (Durst, USA), Dial (Ciba-Geigy, Switzerland); it is contained in Spasmo-Cibalgine (Ciba, Switzerland).

Vinylbital [*2430-49-1*], vinylbarbital, 5-(1-methylbutyl)-5-vinylbarbituric acid,$C_{11}H_{16}N_2O_3$, M_r 224.27, *mp* 90 – 91.5 °C, is prepared by the reaction of guanidine with the appropriate malonic ester and saponification. It can also be synthesized by the addition of acetylene to 5-(1-methylbutyl)barbituric acid in the presence of zinc stearate [80].

Vinylbital is a medium-acting hypnotic; abuse can cause addiction or habituation.
Trade Names. Bykonox (Byk Belga, Belgium), Optanox, Suppoptanox (Valpan, France), Speda (Byk-Gulden, FRG).

Heptabarb [*509-86-4*], heptabarbital, heptabarbitone, 5-ethyl-5-(1-cycloheptenyl)barbituric acid, $C_{13}H_{18}N_2O_3$, M_r 250.29, *mp* 174 °C; one part dissolves in 13 parts of methanol, 20 parts of ethanol, 13 parts of acetone, 40 parts of diethyl ether, and 5000 parts of water. It is synthesized by the condensation of ethyl(cyclohepten-1-yl)-cyanoacetic ester with urea [81].

This compound is a short- to medium-acting hypnotic; abuse can cause habituation or addiction.
Trade Names. Medomin, Medapan (Ciba-Geigy, Switzerland).

Secbutabarbital [*125-40-6*], secbutobarbital, butabarbital, secbutobarbitone, 5-ethyl-5-(2-butyl)barbituric acid, $C_{10}H_{16}N_2O_3$, M_r 212.24, *mp* 165 – 168 °C; the sodium salt [*143-81-7*], $C_{10}H_{15}N_2NaO_3$, M_r234.23, is a bitter powder; 1 g dissolves in 2 mL of water, and the pH of a 1 % aqueous solution is 9.0 – 10.2. Preparation is described in [82]. Secbutabarbital is a medium- to long-acting hypnotic. It is widely used in the United States as a sedative. Blood levels of 3.5 – 6 mg/100 mL are fatal; abuse can cause habituation or addiction.

Trade Names. BBS (Reid-Provident, USA), Butabarbital Sodium (Parke-Davis, USA), Butabarpal (Philadelphia-Labs., USA), Butamide (Zenith, USA), Buticaps (Carter-Wallace, USA), Butisol (McNeil, USA), Day-Barb (Anca, Canada), Merisyl (Meriot, Canada), Neo-Barb (Neo, Canada), Sarisol (Halsey Drug, USA).

Pentobarbital [*76-74-4*], pentobarbitone, 5-ethyl-5-(1-methylbutyl)-barbituric acid, $C_{11}H_{18}N_2O_3$, M_r 226.28, *mp* 130 °C; the sodium salt [*57-33-0*], $C_{11}H_{17}N_2NaO_3$, M_r 248.26, is unstable in aqueous solution. It is prepared by boiling ethyl-1-methylbutylcyanoacetic ester with guanidine in sodium ethoxide solution and saponifying the product with dilute sulfuric acid [83]. This compound is a short- to medium-acting hypnotic and is more often used as a hypnotic than as a sedative. A dose of more than 3 g can cause death; blood levels of 1 – 2.5 mg/100 mL are fatal; abuse can lead to habituation or addiction.
Trade Names. Neodorm (Minden, FRG).

Pentobarbital sodium: Butylone (Hartz, Canada), Dorminal (Alfasan, Netherlands), Embutal (Abbott, USA), Hypnol (Stickley, Canada), Isoamytal, Isobarb (U.S. Standard, USA), Iturate, Lethobarb (Loveridge, UK), Napental (Beecham, UK), Narcoren (Veterinaria, Switzerland), Nembutal (Abbott, USA), Nova-Rectal (Nova, Canada), Novopentobarb (Novopharm, Canada), Pembule (Novocol, USA), Penbon (Adams, Australia), Pental (Van-Pelt & Brown, USA; Saunders, Canada), Pentone (Faulding, Australia), Pentosol (Chromalloy, USA), Prodormol (Teva, Israel), Sedanox (Troncin, France), Sombutol (Farmos Group, Finland), Somnopentyl (Pitman-Moore, USA), Vetanarcol (Veterinaria, Switzerland).

Pentobarbital calcium: Insom Rapido (Andreu, Spain), Repocal (Desitin, FRG).

Butallyonal [*1142-70-7*], 5-(2-bromoallyl)-5-*sec*-butylbarbituric acid, $C_{11}H_{15}BrN_2O_3$, M_r 303.16, *mp* 130 – 133 °C, slightly bitter crystals, is almost insoluble in water, but soluble in ethanol. The sodium salt [*3486-86-0*], $C_{11}H_{14}BrN_2NaO_3$, M_r 325.15, forms a bitter, crystalline powder and is soluble in water; the pH of a 10 % aqueous solution is ca. 9.5. Preparation is described in [84]. This compound is a short- to medium-acting hypnotic; abuse can cause habituation or addiction.

Trade Names. Pernocton (Riedel De Haen, FRG) Pernoston, Sonbutal (Tutag Pharm, USA).

Vinbarbital [*125-42-8*], 5-ethyl-5-(1-methyl-1-butenyl)barbituric acid, $C_{11}H_{16}N_2O_3$, M_r 224.3, *mp* 161 – 163 °C, forms slightly bitter crystals. Preparation is described in [85]; abuse can cause addiction.

Trade Names. Delvinal (Merck, Sharp & Dohme, USA), Diminal (Astra, Sweden).

Talbutal [*115-44-6*], 5-allyl-5-*sec*-butylbarbituric acid, $C_{11}H_{16}N_2O_3$, M_r 224.25, *mp* 108 – 110 °C, forms slightly bitter crystals. Preparation is described in [86]. This compound is a short-acting hypnotic; abuse can cause habituation or addiction.
Trade Names. Lotusate (Winthrop, USA), Profundol (Promonta, FRG).

Cyclopentobarbital [*76-68-6*], 5-allyl-5-(2-cyclopenten-1-yl(barbituric acid, $C_{12}H_{14}N_2O_3$, M_r 234.25, *mp* 139 – 140 °C, forms slightly bitter crystals and is moderately soluble in hot water. This acid is synthesized by the condensation of urea with the appropriately disubstituted malonic ester [87]. It is a short-acting hypnotic; abuse can lead to habituation and addiction.

Trade Names. Cyclopal (Siegfried, Switzerland), Cyclopental (Pharmacia, Sweden).

Propallyonal [*545-93-7*], 5-(2-bromoallyl)-5-isopropylbarbituric acid, $C_{10}H_{13}BrN_2O_3$, M_r 289.13, *mp* 177 – 179 °C, forms slightly bitter crystals and is moderately soluble in water. Preparation is described in [88]. This drug is a short-acting hypnotic; abuse can cause habituation or addiction.

Trade Name. Noctal (Union Chimique, Belgium).

Secobarbital, 5-allyl-5-(2-pentyl)barbituric acid, $C_{12}H_{18}N_2O_3$, M_r 238.28, *mp* 100 °C, is slightly bitter. The sodium salt [*309-43-3*], $C_{12}H_{17}N_2NaO_3$, M_r260.27, is a hygroscopic, bitter powder; preparation is described in [89]. It resembles pentobarbital but has a shorter duration of action and is especially suitable for injection. Blood levels of 1 – 2.5 mg/100 mL are fatal; abuse can cause habituation or addiction.
